INDEX TO VOLUME CXI.

Abdominal Surgery. Address on abdominal surgery, Tait, L., 328.
Aberdein, R. A correction, 427.
Abortion, treatment of, Sawyer, E. W., 591.
Abscess. Treatment of acute abscess, Smith, 45; subscapular abscess, Blodgett, A. N., 158; pelvic abscess, Caswell, E. T., 303.
Acrania and Spina Bifida, Gannett, W. W., 584.
Actinomycosis in man and in animals, 256; two cases of human actinomycosis, 376.
Adams, J. F. A. Sanitary forest-culture, 173.
Adams, Z. B. Latent acute peritonitis of idiopathic origin; large amount of pus in the abdominal cavity; evacuation; recovery, 482.
Agnew, C. R. Foreign bodies in the eye, 208; a new local anæsthetic (hydrochlorate of cocaine), 400.
Alcohol. Some of the effects of alcoholism, Bruen, E. T., 241.
Alcoholic Disease in children, 597.
Amaurosis. Apparent and real amaurosis, Williams, H. W., 577, 587.
Ambulance Bearer Companies, 306; "militia ambulance bearer companies," Wales, N., 355.
Amidon, R. W. The pathological anatomy of sensory aphasia, 490.
Amory, R. The manufacture of oil of cade, 560.
Amputations at the Rhode Island Hospital from 1868 to 1883, Caswell, E. T., 289; amputations and artificial legs, Douglass, D. De F., 297; amputations at the hip-joint, Bradford, E. H., 561.
Anæsthesia. A new local anæsthetic (hydrochlorate of cocaine), Agnew, C. R., and Noyes, H. D., 400; rapid cocainization, Bradford, H. W., 438; ocular anæsthesia produced by cocaine, Williams, C. H., 440; hydrochlorate of cocaine as a local anæsthetic, 450.
Analysts. An American Society of Public Analysts, 569.
Anatomy. Recent progress in anatomy, Dwight, T., 227; the liberating of the ring finger in musicians by dividing the accessory tendons of the extensor communis digitorum muscle, Forbes, W. S., 601, 612.
Andrews, E. Two cases of gastrotomy, 542; excision of the rectum, 542; lithotripaxy, 543; a new instrument for operating on varicocele, 543.
Aneurism of the left ventricle communicating with the aorta, Hughes, W. E., 63; aneurism of the aorta; empyema, Hughes, W. E., 64; remarks on aneurisms, Robison, J. A., 276.
Anthropophagy, 185; anthropophagy, Tupper, A. M., 236.
Antipyrine, Guttman, P., 162.
Aphasia. The pathological anatomy of sensory aphasia, Amidon, R. W., 490.
Apoplexy. Causes and treatment of apoplexy, Jelly, G. F., 593.
Army. Annual Report of the Surgeon-General, 595.
Arsenic. Cases of arsenical dermatitis, White, J. C., 433.
Asthma Nervosum. Bettman, J., 544.
Atrophy. Unilateral atrophy, Burrell, H. L., 462.
Athletics, college, 280.
Axford, W. L. Median lithotomy for cystitis and hyperæsthetic urethra, 18.
Ayer, J. B. A case of cerebral exhaustion (in the early and recoverable stage) following neuralgia and over-work, 561; facial neuralgia, 563.

Baker, H. M. Cheese poisoning, 279.
Barker, F. Charges brought against him, 615; trial and acquittal, 615, 620.
Barnes, H. J. Epuration of sewage by irrigation and agriculture, 84.
Bartholow, R. Some uses of the chloride of gold and sodium in nervous affections, 7; chronic ileo-colitis and laryngismus stridulus, 286.
Bartlett, J. A theory of cholera, or two theories as to the mode of advance of cholera, 253.
Bartlett, J. W. Casts of the pregnant and non-pregnant uterus, 593.
Barton, J. M. Cystic-papillary adenoma of the neck, 493.
Baths. Free baths in winter, 44; cold baths in the treatment of pneumonia, 160.
Behm, C. Combined version in placenta prævia, 261.
Bequests. Medical bequests, 352.
Berlin, F. A case of supposed extra-uterine pregnancy treated by electricity, 243, 250.
Bettman, B. Hydrochlorate of cocaine as a local anæsthetic, 543.
Bettman, J. Rhinolithiasis, with a report of a case of about forty years' development, 135; asthma nervosum, 544.
Bezzenann, De. An unusual case of rabies in the human subject, 502.
Bibliography. Alexander, W., The Treatment of Backward Displacements of the Uterus and of Prolapsus Uteri by the New Method of Shortening the Round Ligaments, 65; Allen, H., A New Method of Recording the motions of the Soft Palate, 424; Althaus, J., On Sclerosis of the Spinal Cord, 568; Amidon, R. W., A Year Book of Therapeutics for 1883, 41; Amory, R., and Wood, E. S., Wharton and Stillé's Medical Jurisprudence, 88; Bantock, G. G., On the Use and Abuse of Pessaries, 449; Beurmann, The Diagnosis of Sciatica, 46; Billings, J. S., The Principles of Ventilation and Heating, and their Practical Application, 137; Black, G. V., The Formation of Poisons by Micro-organisms, 496; Boston City Hospital, Twentieth Annual Report, 209; Bramwell, B., Diseases, of the Heart and Thoracic Aorta, 567; Chesney, J. P., Shakespeare as a Physician, 374; Clouston, T. S., Clinical Lectures on Mental Diseases, 42; Corning, J. L., Brain Exhaustion, 147; DaCosta, J. M., Medical Diagnosis with Special Reference to Practical Medicine, 375; Fothergill, J. M., The Physiological Factor in Diagnosis, 424; Gibney, V. P., The Hip and its Diseases, 65; Green, T. H., An Introduction to Pathology and Morbid Anatomy, 544; Hart, D. B., The Atlas of Female Pelvic Anatomy, 566; Haynes, C. M., Elementary Principles of Electro-Therapeutics, 208; Hutchinson, J., The Pedigree of Disease, 424; Hutchinson, J. C., A treatise on Physiology and Hygiene, 472; Jones, H. McN., Practical Manual of Diseases of Women and Uterine Therapeutics, 375; Mackenzie, M., Diseases of the Throat and Nose, including the Pharynx, Larynx, Trachea, Œsophagus, Nose and Naso-Pharynx, 496; Martin, A., Pathologie und Therapie der Frauen-Krankheiten nach den in den Ferienkursen Gehaltenen Vorträgen, 566; Massachusetts, Vital Statistics for the Year 1883, 474; Ralfe, C. H., Clinical Chemistry, 18; Ranney, A. L., A Practical Treatise on Surgical Diagnosis, 472; Reese, J. J., Text-Book of Medical Jurisprudence and Toxicology, 374; Rindfleisch, E., The Elements of Pathology, 496; Roberts, F. T., The Theory and Practice of Medicine, 375; Rothacker, W. A., Henke's Atlas of Surgical Anatomy, 423; Stillé, A., and Maisch, J. M., The National Dispensatory, 208; United States Commissioner of Education, Report for 1882-83, 380; United States Surgeon-General's Office, The Fifth Volume of the Index Catalogue, 376; Van Buren, W. H., Lectures on the Principles of Surgery, 472; Wagner, C., Diseases of the Nose, 565; Wellner, G. D., The Medical Graduate and his Needs, 400; Woakes, E., Post-Nasal Catarrh and Disease of the Nose causing Deafness, 41; Wurz, A., Elements of Modern Chemistry, 42; Yeo, M. F., Manual of Physiology, a Text-Book for Students of Medicine, 449; Ziegler, E., A Text-Book of Pathological Anatomy and Pathogenesis, 544.
Biography. Adams, A. B., 192; Adams, J. G., 22; Buckler, R., 288; Byrd, H. L., 552; Chamberlain, C. W., 264; Chamberlain, N. S., 456; Clark, L., 336; Cohnheim, J., 307; Damon, H. F., 312; Dix, J. H., 240; Duncan, C. M., 384; Fisk, S. A., 504; Foster, J., 45; Gray, C. C., 549; Jager, 144; Jarvis, E., 456; Langworthy, F. A., 264; Martin, H. A., 576; Osler, W., 429; Parker, W., 599; Radcliffe, J., 379; Rogers, R. E., 288; Wilson, E., 187; Wing, B. F., 144; Woodward, J. J., 216, 237; Zeissl, H. von, 432; Jarvis, E., 598; Thomas, J. G., 600; Duncan, C. M., 600; necrology for the year, 618.
Birdsall, W. A. Ophthalmoplegia externa progressiva, 9.
Bixby, G. H. A case of menstruation recurring every three months, 299.
Blake, J. G. Epuration of sewage by irrigation and agriculture, 84.
Blodgett, A. N. Subscapular abscess, 158; Prof. Pettenkofer on the cholera bacillus, 502; letter from Paris, 620.
Blyth, A. W. Toxicology in literature, 190.
Boardman, W. E. Labor in a case with contracted conjugate: version and craniotomy, 176, 182; on the use of iodoform insufflation within the uterus in puerperal septicæmia, 246, 251; a case of impetigo herpetiformis, 321.
Bontecou, R. B. Two cases of hæmorrhage into the pons Varolii, 250.
Boston. Health of the city of Boston, 1882-84, 89; milk supply of Boston, 111.; Boston Society for Medical Improvement, 584.
Bosworth, J. H. The three tonsils, some practical suggestions in regard to their structure, function, and diseases, 371.
Bowditch, H. I. The aspirator in pleural effusion, 572.
Bradford, E. H. Functional affections of joints, 395; periosteal sarcoma of the femur, 514; cases of Little's disease, 516; amputation at the hip-joint, 561; report on progress in orthopedic surgery, 604.
Bradford, E. H., and Burrell, H. L. Report on progress in orthopedic surgery, 582.
Bradford, H. W. Rapid cocainization, 438.
Breast. Sunken nipples, Du Bois, 88; microscopic slides from a case of spindle-celled sarcoma of the breast, Schweinitz, G. de, 137.
Bridgeman, G. H. The plaster-posterior splint, 165.
Broncho-Pneumonia. The pathology of broncho-pneumonia, Delafield, F., 484, 493.
Brown, B. Extension in the treatment of diseased vertebræ, 1.
Brown, F. F. Sick headache, 391.
Browne, C. Overpressure in schools, 358.
Bruen, E. T. Some of the effects of alcoholism, 241.
Buckingham, E. M. Subcutaneous injections in intestinal pain; their safety as compared with opiates by the mouth, 415.
Bullard, W. N. A typhoid epidemic at the "North End" (Boston), 55, 60.
Burrell, H. L. A case of strangulated umbilical hernia, 368, 371; unilateral atrophy, 462.
Burrell, H. L., and Bradford, E. H. Report on progress in orthopedic surgery, 582.

Cabot, A. T. Recent progress in surgery, 127; a case of double ovariotomy, 158, 160; a case of multiple calculi in the bladder, 195; antiseptic herniotomy with suture of the peritonæum, 363, 371; "tumors of the bladder," 477.
Cade. The manufacture of oil of cade, Amory, R., 560.
Calculus. A case of multiple calculi in the bladder, Cabot, A. T., 195; a case of calculus in the female bladder; removal by Bigelow's operation, Pinkham, J. G., 416.
Cancer of the body of the uterus, involving the rectum, Minot, F., 323.
Candolle, de. Blue eyes going out, 420.
Canfield, R. M., and Putnam, J. J. A case of acute hemiplegic chorea, with autopsy and remarks, 220.
Canned Food. The safety of canned foods, 377.
Cass (Dresden) and Longshore (Philadelphia). Is intromission necessary to conception? 262.
Caswell, E. T. Amputations at the Rhode Island Hospital from 1868 to 1883, 289; pelvic abscess, 303.
Censors of the Massachusetts Medical Society; the method and standard of examination of candidates, 9.

Chadwick, J. R. A specimen of dermoid cyst of the ovary, 131; gastro-nephritic fistula, 274; extirpation of a retro-renal sarcoma by abdominal section, 388, 393.
Chancellor. The non-contagiousness of cholera and inadequacy of quarantine, 397.
Cheese Poisoning, Baker, H. M., 279.
Chemistry. Report on medical chemistry, Hills, W. B., 178; toxicology in literature, 190; cystin in urine, Fifield, W. C. P., 468.
Children. The summer diarrhœa of children, Smith, J. L., 37; the value of sugar symptoms in the diagnosis of many diseases of childhood, Politzer, L. M., 93; difficult dentition, Lyman, G. H., 182; infant feeding and summer diseases of children, 251; on the prophylaxis and treatment of tuberculosis and scrofulosis in children, Förster, 261; chronic ileo-colitis and laryngismus stridulus, Bartholow, R., 286; acute intussusception in an infant eighteen weeks old, Collier, 286; alcoholic disease in children, 307; mental alienation in young children, Leidesdorf, M., 356; overpressure in schools, Browne, C., 358; prevention of ophthalmia neonatorum, Garrigues, H. J., 477; report on diseases of children, Rotch, T. M., 534; congenital arrest of development, Reynolds, J. P., 561.
Chloral Hydrate, as an antiseptic, Warner, E., 177.
Cholera. The westward course of cholera, 19; the cholera in France, 44; our Boards of Health and the State department on cholera, 67; cholera and sanitary neglect at Toulon, 70; suggestions concerning cholera, 138; treatment of Asiatic cholera, Lathrop, W. H., 142; a theory of cholera, or two theories as to the mode of advance of cholera, Bartlett, J., 253; the treatment of Asiatic cholera in Southern India, Scudder, H. M., 278; the treatment of Asiatic cholera in Southern India, Paoli, G. C., 302; sanitary precautions against cholera, 304; the extension of cholera, 305; the cholera epidemic of 1873, Lathrop, W. H., 331; cholera and rags, 353; the non-contagiousness of cholera and inadequacy of quarantine, Chancellor, 397; report of commission on practical work required for the prevention of cholera in this country, 397; "practical recommendations for the exclusion and prevention of cholera," 402; the parasitic doctrine of epidemic cholera, Flint, A., Sr., 420; ætiology and propagation of cholera, Shattuck, G. B., 457; cholera in Paris, 475; the Asiatic cholera at Suspension Bridge in 1854 and its lessons; what we know about cholera, Hamilton, F. H., 491; cholera notes, 497; cholera and rags, 498; cholera in Paris, 499; Prof. Pettenkofer on the cholera bacillus, Blodgett, A. N., 502; precautions against cholera, 550; the cholera epidemic in Paris, 620.
Chorea. A case of acute hemiplegic chorea: with autopsy and remarks, Canfield, M., and Putnam, J. J., 220.
Bylous Deposit in the abdomen, Nickerson, F., 152.
Circulatory System. Aneurism of the left ventricle communicating with the aorta, Hughes, W. E., 33; aneurism of the aorta; empyema, Hughes, W. E., 64; the diagnosis of mitral constriction, 165; report on progress in thoracic diseases, Shattuck, F. C., 205; two cases of hæmorrhage into the pons Varolii, Bonteeou, R. B., 250; remarks on aneurisms, Robison, J. A., 276; double pneumonia in a man with slight aortic stenosis of long standing and possible atheroma of the coronary arteries, Cutler, E. G., 469; pneumonia complicating chronic endocarditis and acute pericarditis, Cutler, E. G., 470.
Clarke, E. C. Epuration of sewage by irrigation and agriculture, 81.
Clevenger. Dr. Clevenger on political abuse of the insane, 523.
Climate. Notes on Nassau as a winter resort, Osgood, H., 155.
Cocaine. A new local anæsthetic (hydrochlorate of cocaine), Agnew, C. R., and Noyes, H. D., 400; rapid cocainization, Bradford, H. W., 438; ocular anæsthesia produced by cocaine, Williams, C. H., 440; hydrochlorate of cocaine as a local anæsthetic, 450; hydrochlorate of cocaine, Holt, E. E., 501; hydrochlorate of cocaine in genito-urinary, eye, and throat surgery, Cabot, A. T., 515; cocaine in ophthalmic surgery, Jeffries, B. J., 537; hydrochlorate of cocaine as a local anæsthetic, Bettman, B., 543; cocaine hydrochlorate in the larynx, Knight, F. I., 550; hydrochlorate of cocaine subcutaneously, Croston, J. F., 573; the use of cocaine in the nose, Hooper, F. H., 585; hydrochlorate of cocaine, Williams, C. H., 585.
Coggin, D. A concretion in the external auditory meatus, 181.
Colic. Local temperature in biliary colic, Cyr, J., 454.
Collier. Acute intussusception in an infant eighteen weeks old, 286.
Conservative Progress, Didama, H. D., 529.
Conservative Surgery, Frisbie, J. F., 476.
Cordeiro, F. J. B. The value of probabilities in medical research, 169.
Coroners, an act relating to medical examiners and coroners, 43.
Corrosive Sublimate. The risks of corrosive sublimate injections, 93.
Cows. The spaying of cows and pure milk, 67.
Crayon. A plea for the use of the crayon in medical schools, Hopkins, G. G., 598.
Croston, J. F. Hydrochlorate of cocaine subcutaneously, 573.
Crow and the Country Doctor, 478.
Crowell, J. The physician a popular educator, 49, 73, 97.
Curtis, H. A sanitary towel, 182.
Cushing, B. Removal of the placenta after abortion, 275.
Cutaneous System. Treatment of the vegetal parasitic skin diseases, 114; a case of xanthoma multiplex, Hardaway, W. A., 230; a clinical study of lupus erythematosus as it affects the hand, Hyde, J. N., 230; a suggestion concerning the treatment of acne and acne rosacea in the male subject, Sherwell, S., 230; a case of unilateral chromidrosis (?), White, J. C., 231; cases of arsenical dermatitis, White, J. C., 231; dermatitis herpetiformis, and its relations to impetigo herpetiformis, Duhring, L. A., 231; a case of late cutaneous syphilis (acne-form syphiloderm of the nose), illustrating the occasional necessity of large doses of potassium iodide, Stelwagon, H. W., 232; a case of vitiligo involving the whole surface, Stelwagon, H. W., 232; a case of general idiopathic atrophy of the skin, Hardaway, W. A., 232; miliaria and sudamina, Robinson, A. R., 232; on a peculiar ringed affection of the glans and prepuce, Taylor, R. W., 232; a case of impetigo herpetiformis, Boardman, W. E., 321; cases of arsenical dermatitis, White, J. C., 433; progress in dermatology, Tilden, G. H., 465; ophthalmic symptoms accompanying impetigo herpetiformis, Greenough, F. B., 472; prevalence of scabies, Greenough, F. B., 514.
Cutler, E. G. Double pneumonia in a man with slight aortic stenosis of long standing and possible atheroma of the coronary arteries; recovery, 469; pneumonia complicating chronic endocarditis and acute pericarditis, 470.
Cyr, J. Local temperature in biliary colic, 454.

Dana, C. L. Folie du doute and mysophobia, 9.
Davenport, F. H. Recent progress in gynecology, 156.
Day, A. Medical delusions, 145.
Death, Punishment by hanging, 191.
Defoe. Defoe upon the plague in London, 213.
Déjérine. Disseminated sclerosis, 287.
Delafield, F. The pathology of broncho-pneumonia, 484, 493.
Delaunay (Paris). Crossing the legs, and the mode of sitting, 429.
Delusions, Medical, Day, A., 145.
Dentistry. Retoration of gums about loose teeth, Rollins, W. H., 22; causes of discoloration in gold fillings in teeth, Rollins, W. H., 226; a gas furnace for firing dental enamels and porcelains; causes of "gasing" in firing teeth, Rollins, W. H., 393.
Diabetes. A case of diabetes insipidus, Fisk, S. A., 105; case of acute diabetes of unknown duration, Rogers, O. F., 208.
Didama, H. D. Conservative progress, 529, 563.
Dietetic Delusions; their deleterious effects, and their rectification, Hodges, R. M., 25.
Digestive System. Significance of jaundice in diagnosis, Quine, W. E., 15; the summer diarrhœa of children, Smith, J. L., 37; a case of chylous deposit in the abdomen, Nickerson, F., 152; gastro-nephric fistula, Chadwick, J. R., 274; acute intussusception in an infant eighteen weeks old, Collier, 286; chronic ileo-colitis and laryngismus stridulus, Bartholow, R., 286; two cases of general chronic proctitis, Johnson, F. W., 295; the dry diet cure of dyspepsia, 329; the absorption of sugar and albuminoids by the stomach, Smith, R. M., 337; antiseptic herniotomy with suture of the peritoneum, Cabot, A. T., 363, 371; a case of strangulated umbilical hernia, 368, 371; the three tonsils, some practical suggestions in regard to their structure, function, and diseases, Bosworth, J. H., 371; dilatation of the stomach, 425; atonic dilatation of the stomach, 473; latent acute peritonitis of idiopathic origin, Adams, Z. B., 482; two cases of gastrostomy, Andrews, E., 542; excision of the rectum, Andrews, E., 543; double inguinal hernia in a male infant thirty-eight days old; strangulation on the left side; herniotomy, Steinbach, G. W., 569.
Dilatation of the Stomach, 425.
Dime Museums and venomous serpents, 209.
Diphtheria. The relations between scarlatina and diphtheria, 70; diphtheria spread by adults, Jacobi, A., 355; "Diptheria spread by adults," Kellogg, D. S., 405; an unusually protracted case of diphtheria, Wins, 464; is the operation of tracheotomy in diphtheritic croup dangerous? when should the operation be performed? Winters, J. F., 588.
Dispensary doctor as Saint Stephen, 570.
Doctors. Three doctors in fiction, 142.
Doe, O. W. Placenta prævia, 182; cranial bones of a fœtus removed from the rectum, 208, 275.
"Doubting Madness," Dana, C. L., 157.
Douglass, D. De F. Amputations and artificial legs, 297.
Draper, F. W. A case of homicide by a wound of the vulva, 217.
Drowning. Notes of a case of drowning, Stedman, G., 177.

Musicians. The liberating of the ring finger in musicians by dividing the accessory tendons of the extensor communis digitorum muscle, 601, 612.

Myers, S. O. Rubber catheter broken off in the uterus, 303.

Myxœdema. A case of myxœdema, West, E. G., 50, 60.

Nancrede (Philadelphia). Specimens from a case of resection of the humerus, 157.

Nasmyth. A fracture of skull of medico-legal interest, 428.

Nassau. Notes on Nassau as a winter resort, Osgood, H., 555.

National Board of Health, 160, 396; a proposal for a new national health organization, 594.

Necrology for the year, 618.

Nepotism at the Massachusetts General Hospital, 117, 164, 283.

Nervous System. Encephalic nomenclature, Wilder, B. G., 6, 7; can locomotor ataxia be cured? Hammond, G. M., 6; multiple neuritis, Webber, S. G., 6; some uses of gold and sodium in nervous affections, Barthelow, R., 7; the relations between injuries of the spinal cord and the excretion of carbonic anhydride, Ott, I., 7; a contribution to the study of hysteria bearing on the question of oophorectomy, Walton, G. L., 8; the medico-legal significance of typical so-called hysterical symptoms occurring in men after railway and other injuries, Putnam, J. J., 8; double hemiplegia, McNutt, S. J., 9; ophthalmoplegia externa progressiva, Birdsall, W. A., 9; locomotor ataxia and syphilis, Seguin, E. C., 9; folie du doute and mysophobia, Dana, C. L., 9; stretching the intercostal nerves, 20; a case of epileptic automatism, 22; traumatic sciatica and its relation to hip disease, Massey, G. B., 86; electric neurosis, 113; the treatment of epileptiform neuralgia by nerve stretching, Waisham, 180; male hysteria, 214; a case of acute hemiplegic chorea; with autopsy and remarks, Canfield, R. M., and Putnam, J. J., 220; two cases of hæmorrhage into the pons Varolii, Bontecou, R. B., 250; report on nervous diseases, Webber, S. G., 271; poliomyelitis in the adult, Van Duyn, J., 285; disseminated sclerosis, Dejerine, 287; a case of epileptic mania, Hall, D. G., 327; sick headache, Brown, F. F., 391; the therapeutical effect of the internal administration of hot water in the treatment of nervous diseases, Ranney, A. L., 389; the pathological anatomy of sensory aphasia, Amidon, R. W., 490; sunstroke; chronic meningitis, Wood, H. C., 505; case of hysterical hemianæsthesia, convulsions, and motor paralysis, brought on by a fall, Walton, G. L., 558, 561; a case of cerebral exhaustion (in the early and recoverable stage) following neuralgia and over-work, Ayer, J. B., 561; facial neuralgia, Ayer, J. B., 563; causes and treatment of apoplexy, Jelly, G. F., 563.

Neuritis. Multiple neuritis, Webber, S. G., 6.

New York Post-Graduate Medical School and Hospital Clinical Society, 613.

Nice. Sanitary condition of Nice and the Riviera, 380.

Nickerson, F. A case of chylous deposit in the abdomen, 152.

Nobiling. Suicide by hanging, 379.

Nomenclature. Encephalic nomenclature, Wilder, B. G., 6, 7.

Nose. The cure of crooked noses by a new method, Roberts, J. B., 369.

Noyes, H. D. A new local anæsthetic (hydrochlorate of cocaine), 400.

Obesity. The pathology of obesity, Kisch, 238.

Ogston, F. A case of scarlet fever in a canary, 381.

Oil. The oil-spot, 429.

Ophthalmia Neonatorum, prevention of, Garrigues, H. J., 477.

Orthopræxy. Extension in the treatment of diseased vertebræ, Brown, E., 1; the cure of crooked noses by a new method, Roberts, J. B., 369; report on progress in orthopedic surgery, Bradford, E. H., and Burrell, H. L., 582; recent progress in orthopedic surgery, Bradford, E. H. 604.

Osgood, H. Notes on Nassau as a winter resort, 555.

Otis, E. O. Penetrating gun-shot wound of the neck, 269.

Otis, W. J. A new powder blower, 81.

Ott, I. The relations between injuries of the spinal cord and the excretion of carbonic anhydride, 7.

Ovarian Cyst. Pregnancy and ovarian cyst; ovarian tumor in a woman of ninety years, Giddings, W. P., 417.
Ovary. A contribution to the study of hysteria bearing on the question of oophorectomy, Walton, G. L., 8; papillomatous multilocular cysts of both ovaries, Parkes, C. T., 18; a case of dermoid cyst of the ovary, Chadwick, J. R., 131; a case of double ovariotomy, Cabot, A. T., 158, 160
Ovulation, Coition, and Impregnation. Garrigues, H. J., 95.
Oyster mistaken for a Malignant Growth, Theobald, 358.

Paddock, F. K. Dr. J. Collins Warren's new operation for rupture of the perinæum through the sphincter, 80.
Paget, J. The national value of public health, 69.
Palmer, C. D. Value of abdominal section as a means of diagnosis, 347.
Paoli, G. C. The treatment of Asiatic cholera in southern India, 302.
Paraldehyd, 116.
Paris. Cholera in Paris, 475; the cholera epidemic in Paris, 620.
Parkes, C. T. Papillomatous multilocular cysts of both ovaries, 18.
Partridge, E. L. Erysipelas, 613.
Pathology. Recent progress in pathology and pathological anatomy, Whitney, W. F., 487, 511.
Pepper, W. Tuberculosis of the serous membranes; death; autopsy, 265.
Percussion Sound. The pitch of the percussion sound, Huntress, J., 149.
Peritonitis. Latent acute peritonitis of idiopathic origin, Adams, Z. B., 482.
Perkinsism. Medical delusions, Day, A., 145.
Pettenkofer. The cholera bacillus, Blodgett, A. N., 502.
Pharmacy. Female pharmacists, 115.
Philbrick, E. S. Epuration of sewage by irrigation and agriculture, 82.
Physician a Popular Educator, Crowell, J., 49, 73, 97.
Physiology. Ovulation, coition, and impregnation, Garrigues, H. J., 95; the rescue of Lieutenant Greely and his surviving companions, 161; the relations between injuries of the spinal cord and the excretion of carbonic anhydride, Ott, J., 7.
Pinkham, J. G. A case of calculus in the female bladder; removal by Bigelow's operation, 416.
Pistol-shot Wounds, Fisk, D. B. N., 313.
Placenta Prævia. A case of placenta prævia, mother and child living, Forster, E. J., 126, 131; combined version in placenta prævia, Behm, C., 201; placenta prævia, Doe, O. W., 182.
Plague. Defoe upon the plague in London, 213.
Plaster-Posterior Splint in the treatment of fractures of the leg, Gay, G. W., 76; the plaster-posterior splint, Bridgman, G. H., 165.
Pleuro-Pneumonia. Some studies on the micrococcus of the pleuro-pneumonia of cattle, Dunn, T. D., 610.
Pleuro-Pneumonia and Hog Cholera at New York and Long Island, 570.
Pneumonia. Cold baths in the treatment of pneumonia, Kiseleff, M. K., 160.
Pneumo-Thorax, Lyman, G. H., 585.
Poisons. The risks of corrosive sublimate injections, 93; dime museums and venomous serpents, 209; some of the effects of alcoholism, Bruen, E. T., 241; cheese poisoning, Baker, H. M., 279; notes of a case of poisoning from Mrs. Winslow's soothing syrup, 370; the safety of canned foods, 377; poisoning by canned foods, Johnson, J. G., 478; nitrite of amyl as an antidote in strychnia poisoning, Hare, H. A., 481.
Poliomyelitis in the Adult, Van Duyn, J., 285.
Politzer, L. M. The value of single symptoms in the diagnosis of many diseases of childhood, 93.
Practice of Medicine. Medical delusions, Day, A., 145; the wisdom and constitutionality of state regulation of the practice of medicine, 522.
Pratt, W. The mortality of married life, 46.
Pregnancy, Affections connected with. Report on obstetrics, Green, C. M., 58; Dr. J. Collins Warren's new operation for rupture of the perinæum through the sphincter, Paddock, F. K., 80; a case of acute hydramnios, with remarks on the pathology of this affection, Green, C. M., 121, 130; a case of placenta prævia, mother and child living, Forster, E. J., 126, 131; antiseptic midwifery at the Dublin Rotunda Hospital, 138; labor in a case with contracted conjugate version and craniotomy, Boardman, W. E., 176, 182; placenta prævia, Doe, O. W., 182; a case of supposed extra-uterine pregnancy treated by electricity, Berlin, F., 243, 250; combined version in placenta prævia, Behm, C., 201; is intromission necessary to conception? Cases, Longshore, 262; concerning the etiology and pathology of hydramnios, Green, C. M., 267; cranial bones of a fœtus removed from the rectum, Doe, O. W., 268, 275; a case of retroversion of the gravid uterus, Elliot, J. W., 275; removal of the placenta after abortion, Cushing, B., 275; hydramnios in extra-uterine pregnancy, Teuffel, R., 287; missed abortion; sclerosis of the placenta, Garrigues, H. J., 333; extra-uterine pregnancy, Thomas, 347; tubal pregnancy, Maury, 348; the present aspect of the puerperal diseases, Smith, A. H., 349; the occipito-posterior position in vertex labors, Sawyer, 349, dystocia from coiling of the cord about the neck of the fœtus, Rachel, 381; obstinate vomiting of pregnancy; induced abortion; recovery, Fifield, W. C. B., 394; placenta succenturiata, Richardson, W. L., 394; pregnancy and ovarian cyst, Giddings, W. P., 417; sudden death in child birth, Lusk, W. T., 430; a fatal case of puerperal convulsions preceded by excessive epigastric pain, Goss, F. W., 464, 471; summary of six hundred consecutive cases of midwifery, Wellington, W. W., 509, 516; case of extra-uterine pregnancy; rupture; peritonitis; recovery, Montgomery, E. E., 540, 548; a case of extra-uterine pregnancy treated successfully by electricity, Sibbald, J., 511, 518; some points regarding puerperal convulsions, Withington, C. F., 580; treatment of abortion, Sawyer, E. W., 591; casts of the pregnant and non-pregnant uterus, Bartlett, J. W., 593.
Presbrey, S. D. Notes of two autopsies, 154.
Preventive Medicine for the autumn, 451.
Prizes. The Fiske prizes, 44; Lomb prizes, 419.
Probabilities. The value of probabilities in medical research, Cordeiro, F. J. B., 169.
Proctitis. Two cases, Johnson, F. W., 295.
Profession. An over-crowded profession, 90.
Progress. Conservative progress, Didama, H. D., 529.
Providence. Disposal of sewage at Providence, a sewage besieged city; 596.
Puerperal Convulsions. Some points regarding puerperal convulsions, Withington, C. F., 580
Putnam, J. J. The medico-legal significance of typical so-called hysterical symptoms occurring in men after railway and other injuries, 8.
Putnam, J. J., and Canfield, R. M. A case of acute hemiplegic chorea, with autopsy and remarks, 220.
Pyosalpynx. A successful case of abdominal section for pyosalpynx treated by Volkmann's method, Martin, F. A., 132.

Quarantine. Efficacy of quarantine and the rights of states, Rauch, J. H., 395; the non-contagiousness of cholera and inadequacy of quarantine, Chancellor, 397; report of committee on practical work required for the prevention of cholera in this country, 397; the follies of quarantine, 403; quarantine as a sieve, 524; the quarantine conference in New York, 547.
Questions. The diagnostic use of questions, 233.
Quine, W. E. Significance of jaundice in diagnosis, 15.

Rabies in the human subject, Beurmann, M. de, 502.
Rachel. Dystocia from coiling of the cord about the neck of the fœtus, 381.
Ranch Life. The drawbacks of ranch life for the phthisical, Fisk, S. A., 46.
Ranney, A. L. The therapeutical effects of the internal administration of hot water in the treatment of nervous diseases, 399.

EXTENSION IN THE TREATMENT OF DISEASED VERTEBRÆ.[1]

BY BUCKMINSTER BROWN, M. D.

QUESTIONS have been sometimes asked me in regard to the origin and first employment of extension in the treatment of caries of the spine.

The first case of spinal caries in the treatment of which I have a record of the use of horizontal extension and counter-extension occurred in January, 1864.

At the period referred to the teaching of the highest authorities and of the text-books was that any attempt at extension was unjustifiable, and that the use of any means to prevent pressure together of the bodies of the diseased vertebræ or to separate them, however slightly, rendered a cure impossible. Sir Benjamin Brodie goes so far as to say that in cases where the disease has existed a long time the patient should be "supported by cushions and pillows so that the position in which he is placed may have no tendency to restore the spine to its original figure." He continues: "In the management of these cases it is important that we should always bear in mind that without undue interference on the part of the surgeon the carious or ulcerated surface of the vertebra above will come in contact with that of the vertebra below, and that it is to the union which takes place between them under these circumstances, at first by soft substance and afterwards by bony anchylosis, that we are to look for the patient's recovery. In artificially straightening or elongating the incurvated spine we necessarily disturb this curative process, and therefore all attempts to do so, whether by machinery or by laying the patient in the supine posture on a horizontal board, are to be scrupulously avoided." [2]

Mr. Samuel Cooper, in his First Lines of Surgery, coincides with Sir Benjamin Brodie, and quotes him in corroboration of his own views.

Sir Astley Cooper says "That the mode in which the disease becomes cured is by the upper portions of the vertebræ falling on the lower, and in this way anchylosing. This must be your object in the treatment of this disease." . . . "As to avoiding deformity, that is out of the question; in all these cases deformity is inevitable; whatever you do this cannot be prevented." [3]

"The incurvation forwards," says Lawrence, "is necessary to fill up the deficiency produced by ulcerative absorption." [4]

I was first led to deviate from the instruction of these high authorities in regard to treatment by the occurrence of the case I have mentioned. The patient was a girl seventeen years of age. The disease was in the dorsal vertebræ, and was attended by excruciating pain night and day.

My notes of the case are: "Four vertebræ projecting. Excessive incurvation in lumbar region, to such a degree as almost to throw the body from its balance backward. Constant pain; debility; emaciation. Protuberance and incurvation constantly increasing."

Perfect rest, — immobilization, in fact, — counter-irritants, combined with other measures which have usually brought relief, were of no avail. The pain continued without mitigation.

Thus disappointed it occurred to me that in hip disease, a disease of similar structures to those of the spine, it is the general experience that relief to pain is often, almost uniformly, obtained by extension or by separation, so far as the anatomy of the parts admit, or, at any rate, by preventing pressure on the diseased tissues. From analogy why should not stretching of the muscles and ligaments connected with the carious or inflamed vertebral joints in like manner, by lessening internal pressure, relieve suffering?

In conformity with this theory I applied a padded leather belt around the pelvis. This belt had straps on each side extending from over the iliac bones towards the foot of the bed, terminating in loops. Through each of these loops was passed a cord to which a weight was attached, one on each side. The bedstead being tilted towards the head the upper portion of the body served for counter-extension. Since that time I have sometimes, for this purpose, made use of a padded belt around the chest, below the arms, and attached to the head-board. Soon after the application of the weights the pain was relieved. The directions given were that they should only be used during the day. The relief was so great that the patient requested that the extension should be continued night and day.

In treating these cases it has, for many years, been my plan to have a small pillow or pad placed under the projecting or diseased portion of the spine. This pad serves as a fulcrum. The upper portions of the body above the curvature and the lower portions below act as levers [5] by which the diseased surfaces are prevented from coming in contact, or at least pressure of these surfaces is removed, and the spine is more or less straightened. This fulcrum I had been in the habit of using previously to the case here referred to, and both of these measures have been employed in every case to which they appeared applicable since the date I have mentioned. In the case above described the cure was perfect. My memorandum of this case on July 9th says: "Patient has continued to improve. Has had no pain in back since use of weights. Projection and incurvation have gradually lessened. Has gained flesh rapidly. Is in good spirits. Applied, to-day, spinal body apparatus." From this date she began to sit up and walk.

The patient went out to service, and was afterwards married.

The second case in which I employed this method came under my care in May of the same year (1864). The patient was a girl four years of age. Three dorsal vertebræ were diseased. "Treatment: weights to the hips; counter-extension by means of a strap around the chest, and attached to the head of the bedstead." My next memorandum is dated August 6th. "Spinal protuberance lessened. General health greatly improved."

In this case the result was complete restoration to health.

In 1873 I received a visit from this patient after an interval of nine years. She was in perfect health, had no deformity except slightly rounded shoulders, and this was the only vestige that remained of the disease from which she had suffered.

[1] Under this term, as here used, lateral curvature and kindred affections are not included.

[2] Diseases of the Joints, page 266.

[4] Supra citation.

[5] Of power proportioned to the thickness of the pad, which should never be very thick.

In cases of disease of the cervical vertebræ the success which has attended extension continued night and day for months has been remarkable both in the complete removal of the curvature and also in the relief and comfort afforded to the patient. In the treatment of caries in this region the straps by which extension is made are an important item. They should be of soft leather, well padded, and carefully fitted to the occiput, and so shaped to the chin as to avoid the liability of slipping back against the throat. Of late I have used head gear similar to that employed by Dr. Sayre in connection with his suspension tripod, and have found it answer well. Where the disease is in the neck or in the cervico-dorsal region the bed should be perfectly level or sloped gently towards the foot.

A recent case, treated during the spring and summer of 1883, was a striking example of the efficacy of continued extension in cervical caries.

The patient was a boy four years old. He was injured in May, 1882, by a sheep butting his head and neck. He was taken up insensible. Unmistakable evidence of disease was not manifested until the succeeding winter. The child when first brought to me, in March, 1883, was never free from suffering. His countenance bore the marks of great distress. His head was thrown backward, the occiput resting upon the upper dorsal vertebræ. So deep was the sulcus thus formed, and so forcibly was the head drawn back, that it was impossible, without the use of unjustifiable force, to insert the finger for the purpose of testing the sensitiveness of the bones. The action of the vesical sphincter was impaired.

The head gear and weight were at once applied with the effect of relief from pain. The neck was gradually elongated, and the head brought to its natural position. The child became playful and happy. From a state of utter misery he was changed to one of enjoyment; laughing and amused through the day, and sleeping well at night. He had a bench placed across his bed, on which were his toys, etc.

I had a pulley attached to one end of one of Dr. E. H. Bradford's steel bed-frames. This frame I have found a great convenience in such cases. On it the child could be moved about, and in summer placed upon the piazza or beneath the shade of trees, and the extension be still continued.

In October, 1883, the patient was discharged from treatment in perfect health, with restored activity, and with a normally straight neck.

During these months the weight had been suspended to his head almost without intermission. In a letter received from his mother in September, she says: "The little boy is doing splendid. So far as I can see his neck and back are as perfect as any one's." Another letter, received February 18, 1884, gives information of the boy's uninterrupted good health.

This is in brief the history of the introduction of the present treatment of spinal disease by extension. By it I know that much has been and much can be accomplished. It certainly appeared to be carving out a new path when these changes were first introduced in the approved methods of treatment. The course of treatment by complete rest and extension which was adopted in the cases above cited is not applicable to every instance of vertebral disease. The judgment of the practitioner must be relied upon in the selection of those cases to which it is appropriate. But I would here testify from experience that the large majority of patients suffering from caries of the spine have a far more favorable chance for complete restoration if such a course is pursued during a certain period of the disease than by any other method. And still more forcibly would I say that cervical disease treated in the way above indicated will be attended by a success as regards comfort and symmetry which cannot be attained by a course which relies upon the use of instruments in the upright position.

I do not intend it shall be inferred from what I have said that the cases related in the previous pages were the first in which extension had been used in the treatment of diseased spine. Samuel Hare, of London, in 1849, and E. W. Tuson in 1841, employed extension in the treatment of spinal disease. R. W. Bampfield in 1845 advocates this measure in excurvation of the spine, under which head he appears to class simple excurvation and also curvature from disease.

But, on the other hand, this writer says: "Instruments for stretching and supporting the vertebral column should not be employed during scrofulous or simple inflammation or caries, or vertebral destruction by absorption; neither should they be resorted to during the regeneration of bone."[1]

During the twenty years more or less which had elapsed from the period of these publications to 1864, the date of the first case related in this paper, the English authorities taught, as we have seen, apparently on theoretical grounds, a course opposed to extension. In America it had not I think been practiced until employed by me in 1864. Horizontal extension was then resorted to primarily for the relief of pain, and I considered it an original suggestion, so applied. The prevention, removal, or diminution of deformity was then secondary, although they have since become equally important, results.

R. Volkman, in a monograph published in 1868, speaks of the beneficial effects to be derived from extension in the recumbent position in caries of the spine, and I am gratified that his experience likewise coincides with mine, especially in regard to the relief from pain frequently afforded by this method.[2]

Reference has been made to the usefulness of a narrow pillow or pad beneath the prominent vertebræ. In this connection I will mention that in hip disease a similar pillow under the pelvis operates likewise as a fulcrum, the trunk being the extending power above and the leg with weight attached to it below, thus tending to prevent contraction at the groin.

The constitutional remedies suitable to these and similar cases have not here been dwelt upon. Attention to this point should on no account be neglected. Every case at some period requires the aid which can be derived from appropriate remedies judiciously administered. Flying blisters, very small, will often lessen the tenderness of the bones and of the surrounding parts, and relieve the costal, gastric, and abdominal pains which almost uniformly attend the earlier stages of the disease. Iron and cod-liver oil will frequently be of service. Stimulants, small quantities of wine or brandy, are required in certain conditions of the system and afford help which can be derived from no other remedy.

The syrup of the lacto-phosphate of lime is a convenient means by which an essential constituent in the

[1] Essay on Curvatures and Diseases of the Spine, London, 1845, page 93.

[2] Gelenk entzündung und Gewichts extension. 1868.

formation of bone can be introduced into the economy in a manner easily assimilated. The discovery of this preparation several years since by M. Dusart has contributed an auxiliary which, theoretically at least, should be of important service in our treatment of diseased bone.

The preparations of lime in some of the various forms in which they are presented to us I had previously employed, but with no gratifying results. Not infrequently the remedy passed through the system unchanged. The lactic-acid solution is readily acted upon by the absorbents, is withal an agreeable medicine, and supplies an element which is required, and the use of this remedy in practice has appeared to be attended with decided benefit.

SIX GENERIC DRUG MODIFICATIONS.[1]

BY HENRY M. FIELD, M. D.

As respects idiosyncrasy in the action of the *alkaline bromides*, a closer analogy obtains with what we observe in the drug just discussed than might be expected when we consider difference both of physiological influence and of therapeutical uses. We can devote but one remark to this subject, however. Professor Duhring distinguishes eight varieties of skin disease as characteristic, in different individuals, of bromide saturation, namely, three varieties of acne, a brownish discoloration of the skin, a simple papular eruption, maculo-papules, bullæ, and rupia. To these Dr. Seguin adds a ninth, which he carefully describes, — a semi-malignant looking ulceration upon the lower part of the leg. Of course these results are mostly confined to the practice of neurologists who use maximum doses, as in epilepsy, cerebral tumor, etc.

I might speak of the propensity of chloral hydrate to "fly to the eyes," as it has been called, — and, indeed, shall have a word on this subject a little later, — and this, after moderate and brief use, producing severe conjunctivitis, etc., and, in exceptionally severe cases, photophobia and œdema of surrounding parts; a phenomenon which is now and then observed in less degree from the continued use of the bromides. Carbolic acid appears to be well nigh controlled by individualism, and to such extent that many writers have questioned whether so powerfully toxic an agent should be used at all, at least to the extent of the production of a perceptible physiological impression.

Here it seems pertinent to introduce the following note: It is generally assumed that idiosyncrasy is a fact both of heredity and transmission, and this is doubtless true; that with various modifications in degree of development, as, for example, an especial prominence at times of weakness or ill-health, it exists as a permanency at least throughout the life of the individual. I have, however, a case at present under observation which shows the actual genesis of an idiosyncrasy *de novo*. My patient is a female of strongly marked neurotic character, made such, indeed, both by inheritance and education. With strong mind and weak nerves, she affords a prominent illustration of that unhappy type in which there appears to be a more or less constant conflict between what has been called the abdominal and the cerebral brain. Four years ago it became necessary to advise the procuring of sleep by a nightly enema of chloral hydrate, in a moderate dose. This was continued for fully eighteen months without material increase in quantity of the hypnotic. It was then stopped, partly because of the appearance of a mild form of conjunctivitis, and accompanying symptoms. After fully two years' suspension, it recently seemed wise again to resort to this measure, and, accordingly, twenty to thirty grains was ordered by enema on retiring. The therapeutic effect was all that could be desired, but at the end of ten days a summons found the patient in a state of great distress. There were conjunctivitis and photophobia, the eyes were nearly closed by surrounding swelling, the face, suffused, red, hot, presented such a degree of œdema that the husband demanded an examination of the urine before he was satisfied that some disease of the kidneys had not set in. Arrest of the chloral for a few days, and then occasional attempts to return to it, established the fact that the case was idiosyncrasic and due to the remedy employed.

I have spoken of carbolic acid as well-nigh controlled by individualism. Busch regards it as "one of those drugs which indeed act well in medicinal doses, but to which certain persons, for reasons as yet unknown to us, are so sensitive that quantities harmless to innumerable other persons act poisonously upon them;" and Köster has the alarming suggestion that the occasion of the report of so few deaths under antiseptic treatment is to be referred to the uncertainty of the symptomatology of carbolic-acid poisoning, in different constitutions, and hence the casualty "is concealed under the names shock, collapse, and similar terms." The dangers of carbolic-acid spray are noted in another division of this paper. Deaths from the use of this material, whether as applied to the surface or introduced into the cavities of the body, under conditions which we have no right to say were not cautious and skilled, have taught us that a remedy so capricious is not to be used, except under circumstances of the strictest limitation.

Death from chloroform in competent practice is largely to be referred to idiosyncrasy; "we waste our labor when we search for proof of heart disease or some flaw in the apparatus or some want of care in the administration." Again, says Hutchinson, "It is probable that there are persons in whom, owing to peculiarity of nerve-organization and not in the least to anything we can recognize as ill-health, the inhalation of chloroform will always cause a depression of the heart's action.

A rather startling experience of my own with sulphuric ether the past winter has interest in this connection. The subject was a patient and friend of twelve years' acquaintance, was of middle age, robust health, good habits, had no disease of heart or kidneys. The ether was pure and given in confidence for the extraction of a small tumor of the fore-arm. Hardly had anæsthesia been reached when a sudden and an apparently paralyzing action was exerted upon the respiratory centre, with the production of symptoms which seemed to demand the immediate suspension of the anæsthetic and involved an incomplete performance of the operation intended.

But once again: We do not need to invade the mysteries of the interior of the body in the search for illustrations of our subject; we have but to observe the varied phenomena of medication applied to its surface. The application of the tincture of iodine to the skin should produce only an erythema, but there are subjects with whom it causes vesication and an extensive

[1] Continued from vol. cx., page 606.

œdema. Now and then, indeed, it seems impossible to cause any impression, however often it may be applied. But remote and profound constitutional effects may follow from what was directed for topical external influence alone. Thus Buckell reports that "in the case of a lady, who had the tincture of iodine very lightly painted upon a tumor between the scapulæ, there appeared pain and a sense of oppression in the epigastric region and also trembling, weakness, profuse sweating, dribbling of urine, and inability to stand erect. The use of stimulants and application of warmth over the stomach caused these symptoms to disappear in a few days." Here there was wide departure from what should be looked for had even the iodine been administered internally and in toxic dose.

I was called within the year to see a female patient who had believed herself for two days to be suffering from an attack of the measles; but when to an extensive eruption, which showed no disposition to disappear, there were added a degree of blindness, confusion of thought, headache, etc., alarm was taken and the physician called. Almost the first condition noted, after the first general survey, was wide and fixed dilatation of the pupils. Inquiry elicited the fact that the patient had been wearing for several days past a four by six inch perforated belladonna plaster to the small of the back, nor did the subject by any means present the usual type of exceptional susceptibility to belladonna.

But it is not alone in the skin as respects medicines applied to the skin; the phenomena of individualism may be encountered within even narrower limits. An inert ointment made of fresh fat, applied with no extreme degree of friction, will develop inflammation of the cutaneous surface with some subjects, whereas the local phenomena attending the application of a mild oleate of mercury are so varied that it is safe to predict nothing with certainty.

So much for idiopathic idiosyncrasy, which, after all, could probably in every instance be shown to be anatomical as well, as truly as in the instance already cited, could we apply the requisite knowledge in our study of the question. It is anatomical, or rather physiological, idiosyncrasy which explains certain of the more familiar eccentricities in the behavior of iodide of potassium; the usual rapid, exodic elimination does not obtain; the salt is brought back by the salivary glands, and in the nasal and bronchial mucus, to be reabsorbed or again swallowed, and thus a kind of *vicious circle* is soon set up with attendant coryza, foul breath, foul taste, etc. Had we a more intimate knowledge of that wonderful congeries of ganglia and connecting nerve filaments, the solar plexus and its associated systems, — wisely called by the ancients *cerebrum abdominale*, — we might often avert or control what is now unexpected, disastrous, or inexplicable in the operation of our more powerful remedies.

With this we must leave what for lack of a better name we call idiopathic idiosyncrasy; there is also what Mialhe has happily designated a *chemical idiosyncrasy*, due to "difference in composition of the animal fluids." The very opposite behavior of subnitrate of bismuth was for a long time a problem with therapeutists. Usually producing the local sedation for which it was given, it would occasionally be speedily followed by violent irritation and even inflammation of stomach and intestines. The theory that such action was due to admixture of arsenic did not abide results of investigation; but it was not until attention was directed to the varying reaction of the gastric mucus that the mystery received explanation. An excessive quantity of acid present in the stomach is capable of causing the conversion of the "intrinsically harmless basic salt into the corrosive neutral body; or, in consequence of the action of water upon the latter, into the poisonous acid salt."[1] These are active poisons, capable, as Orfila showed in his experiments upon animals, of producing intense gastro-enteritis.

The operation of calomel presents great variety. It has not been always safe, in my experience, to order so small a dose as one twelfth grain repeated every two hours; this minute quantity, so taken that the aggregate hardly exceeded one half grain, has more than once caused symptoms that simulated cholera morbus, — and this in the case of a vigorous man. Here we must suppose there is fault in the proportion of intestinal alkali and common salt. It has been observed that in patients "who have been long kept upon a low diet calomel has almost no effect, because in consequence of the excessive use of food in a liquid form the greater part of the chloride of sodium has been already washed out of the body." On the other hand, Mialhe asserts that persons who have long lived on a salty diet, as sailors, are "peculiarly sensitive to the action of calomel, and may present exceedingly intense local irritative effects in the intestines as well as a number of other unpleasant effects of mercury." Further, Radziejewski has shown that the long-continued use of calomel may be followed by unpleasant consequences; the drug having accumulated in the cæcum, and having been then brought in contact with chloride of sodium or ammonium, is converted into corrosive sublimate, and corrosion or ulceration follows.[2]

The occasional dyeing of the skin, the peculiar slaty-gray color, which may attend the continued ingestion of silver nitrate, affords a familiar illustration of chemical idiosyncrasy: perhaps there is no other instance where the measure or conditions of its determination have been established with any approach to certainty. Many authors state the time beyond which it is not safe to go, but within the limits of which the metal can be used continuously with reasonable assurance of safety; and it is claimed that thirty grammes, ʒvijss, is the smallest quantity of silver which has been known to produce argyria.

The patient, into whose scrotum I rubbed the oleate of mercury for swelled testicle, presented melancholy evidence of chemical idiosyncrasy for many days thereafter. I did not know that the part had been previously painted with iodine; but the mercury was not slow in discovering the fact, and a very aggressive red iodide of mercury was formed, — as it appeared, penetrating deep into the tissues, — which accomplished about the most effective and protracted counter-irritation that I ever witnessed.

Secondly. It is convenient to group together certain conditions of drug-modification under the section *Cos-*

[1] Lewin.

[2] That should not be imputed to chemical idiosyncrasy which, in time and place, owes its origin, afar from any contact with the patient, to the previous chemical change of the calomel through carelessness of physician or apothecary. It is well to follow the rule that the physician's calomel should be carried in a tightly-stopped vial and unmixed with any other substance. Calomel may pass into the corrosive chloride in presence of the alkaline earths; this should be remembered in combining with magnesia, as is sometimes done. Analysis of calomel pastiles, having sugar for their basis, disclosed a considerable quantity of sublimate. Probably the sugar was "raw;" still it is safer to avoid sugar altogether in preparing calomel powders unless the latter are to be taken forthwith.

mic Conditions, and, still for convenience, in this class to consider the more personal influence of habit. Whatever pertains to latitude, season, temperature, race, etc., must be glanced at in this department. Such general relation is abundantly recognized in the rude medical practice of our forefathers, whose intricate and often mystic ceremonies, both in the collection and the prescribing of their remedies, were quite possibly, in a given case, based alike upon the age of the plant, of the moon, and of the patient. Gubler insists that "cosmic conditions" should be considered in the ordering of so common a remedy as cod-liver oil; which may readily be taken in the cold of winter by the same subject who is wholly unable to continue it through hot weather on account of the disturbance which a fatty substance then occasions, both in the stomach and bowels. Lisfranc says that, of barium chloride, much larger doses are borne in warm climates than in colder regions. The great majority of lead-poisoning cases occur in the summer months, possibly because the metal is largely eliminated by the kidneys, and the functional activity of these organs, in respect of the skin, is then considerably in abeyance.

Again, ethnic conditions present a curious study for the physician. Here, clinical observation has already done somewhat for us; and, in respect of the more familiar remedies, we may know what modification of dose to make, what modification of effect to expect, when we are dealing with a pronounced type, for example, a subject of the Negro or Mongolian race. But while so much in this direction remains undetermined or obscure, we may be pardoned if we look this way for light upon certain questions which, otherwise viewed, seem hopelessly involved. The *Coca erythroxylon* in its effects upon the Indian of South America, as narrated by Von Tschudi and other travelers, would appear to be the very type of a dynaphor. Under its moderate influence the body continues in a state of contented and healthful activity, although the hour for sleep has long since passed and the hour for eating has been more than once pretermitted.[1] Here would seem to be the grand corroborant for the man worn by our modern life conditions, who, out of all his food and sleep, cannot get force enough to carry him through his daily duties with any proper amount of comfort and energy.

But the result of the trial is largely a failure, though it must be acknowledged that, rarely, we get a response which encourages us to persevere with the remedy; and the disappointed practitioner turns upon the South American traveler with the charge of extravagant statement or absolute untruth. That Von Tschudi's statements are extravagant it may be allowed, but they are not thus disposed of. The historical fact remains that when the coca leaf was "first introduced into Europe its marvelous effects encountered a great incredulity; they were attributed to the power of a demon, and coca had the honor of being condemned, successively, by the Jesuit fathers, by the Council of Lima, and by his Catholic Majesty." Doubtless we seldom or never receive the drug in form calculated to display its full effects;[2] but the question is pertinent whether there may not be involved in the earlier observations a very prominent consideration of race, both as respects the aborigine and the volatile, excitable nations of Southern Europe.

Again, we are tempted to ask whether the passage of the years — of the centuries — may have introduced some material modification into the action of remedies which are now regarded as practically valueless, but which our forefathers invested with superior qualifications. Where lies the responsibility for the extraordinary change we note? Is it in the plant, or in man, or in both? Could it have been our saffron — the familiar, largely discarded saffron of the present year of grace — which so eminent a therapeutical authority as Murray extols as equivalent to "opium and wine in combination"? Must it all be ascribed to mingled superstition and ignorance, or to simple long-established prepossession, when the school of Salernum puts its often-quoted aphorism in emphatic interrogative form, How can the man die who grows sage in his garden? ("Cur moriatur homo cui crescitur salvia in horto?") Can this *salutary* sage be nothing more than the *Salvia officinalis* of to-day, more valued in culinary than in medical art?

The modifications occasioned by *habit* are so great that it is not too much to say of the man who, from long habituation as to alcohol, to opium, finds himself literally bound to continue in his accustomed indulgence, — it is not too much to say of him that he is a *changed man*; so changed in certain physical conditions, and it may well be in moral nature also, that it is well-nigh hopeless that he should be comprehended. The friend who, from interest, duty, affection, should extend the helping hand cannot understand him, does not and cannot occupy common ground with him. Hence the helplessness and mischief of much that passes for temperance reform. There would seem to be an essential element in all these cases, as Lewin has pointed out, a craving for the forbidden drug, as one will crave common salt, after long abstinence from it; "just as this, an essential constituent of the body, must be supplied, so has the drug from its habitual use become an integral element for certain organs, and its omission is resented in the same way as would be that of any other elementary constituent of the body." But in an important sense *not* "*in the same way*:" the man who is starved for his food is a wretched sufferer, doubtless; the habitué who is starved for his opium endures a wretchedness which, fortunately, common human experience knows nothing of.

Again, a drug habit will modify the action of other toxics; thus alcohol acts badly with one accustomed to chloral hydrate, and *vice versa*.

A very singular experience is occasionally presented by both the votary of tea and of tobacco, which must probably be referred to the conjoined influence of habit and idiosyncrasy, a fact well-nigh unparalleled in what we observe of the action of other neurotics, although arsenic, in continued medicinal use, may illustrate remotely the same principle. Says Professor Hutchinson: "A man who has drunk tea all his life, and largely, may rather suddenly find that it is almost poisonous to him." So also tobacco with an individual who has used it, it may be, "without any excess, and who has been for a long time thoroughly habituated to it," may all at once begin to act as a poison without causing any distaste or any conspicuous derangement. These subjects are often quite unaware of what it is that is hurting

[1] Indeed, I think I have observed in my own person, in an experience of a daily dose of coca taken for several weeks, an hour before dinner, that, in addition to the sustaining effect which attends its action, the desire for food, the sense of hunger, otherwise existent, is removed for some time.

[2] The drug house of C. F. Rogers, Newton, has recently procured a specimen of coca leaf and prepared a fluid extract, the latter of which is more satisfactory to me than any pharmaceutical preparation of the drug I have yet come across. But I am satisfied, that to get the full effect, the dose should be larger than it is generally stated.

them. They lose appetite and become nervous, and among the most conspicuous symptoms is a very marked failure of sight." There is reason for belief, by the way, that this tobacco amaurosis is most likely to appear in such as originally presented an especially marked idiosyncrasy against tobacco, and in whom the struggle was especially severe and long before the system could be brought to receive it without protest.

(To be concluded.)

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

TENTH ANNUAL MEETING. HELD AT NEW YORK JUNE 18, 19, AND 20, 1884.

SECOND DAY. AFTERNOON SESSION.

ENCEPHALIC NOMENCLATURE.

THE discussion of Professor Wilder's paper on Macroscopic Encephalic Nomenclature being in order, DR. WILDER debated the three principal arguments which he said had been urged against the adoption of the nomenclature which he proposed. These were (1) that some of the terms now in use were indicative; (2) that some were commemorative; and (3) that most of them were familiar. He then read three resolutions, two of which committed the Association to at least a partial adoption of the new nomenclature, which he said would be brought up for discussion at the proper time. Remarks were made by DRS. DANA, BIRDSALL, and WILDER, and, on motion of DR. WM. A. HAMMOND, the resolutions read by the latter were made the special order for miscellaneous business at the next session.

DR. J. LEONARD CORNING, of New York, was elected an active member of the Association.

DR. GRAEME M. HAMMOND, of New York, read a paper entitled

CAN LOCOMOTOR ATAXIA BE CURED?

From time to time, he said, reports of cases cured had been presented to the profession, many of them by men of the highest reputation, and the question therefore arose, Are these true cases of ataxia, or is there some other morbid condition of the spinal cord, which, when present, gives rise to symptoms similar in every respect to those resulting from sclerosis of the posterior columns? He then read the histories of a number of cases which he had collected, after which he passed them in review somewhat as follows: The first case mentioned (which he had presented as cured at the last meeting of the Association, and now again brought before it in person) was certainly a complete cure, and with a single exception (a case reported by Dr. Schultz, of Heidelberg) was the only one in which the tendon reflex had been restored. In the third case there was a complete cure except that the tendon reflex had never been reëstablished. If this was not one of those exceptional cases in which there never was any tendon reflex, this was conclusive proof that some morbid pathological condition still existed in the spinal cord; whether sclerosis, congestion, or something else, no one could tell. In Schultz's case sclerosis existed in both the lumbar and dorsal regions, and yet the patella tendon reflex was present in both legs. It was necessary to conclude, therefore, that the deep reflexes were not always, if ever, transmitted, as was commonly supposed, through the posterior columns, but sometimes passed through the posterior horns of gray matter. A case reported by Desnos, with autopsy, showed that all the symptoms were due to congestion, and it would seem that the symptoms in Schultz's case were attributable to the same cause. A case of Dr. Henry Lyman's, reported in the *Chicago Medical Journal and Examiner*, which was greatly improved by dry cupping and the use of Junod's boot, was undoubtedly relieved by the dissipation of the congestion in the cord. His conclusions were as follows: —

(1.) The absence of the patella tendon reflex in locomotor ataxia is not always caused by sclerosis of the posterior columns.

(2.) Sclerosis of the posterior columns may exist without being accompanied by the ordinary prominent symptoms of ataxia.

(3.) Congestion of the posterior half of the spinal cord may give rise to most, if not all, of the symptoms of locomotor ataxia.

(4.) It is impossible during life to make a differential diagnosis between posterior spinal sclerosis and posterior spinal congestion.

(5.) Posterior spinal congestion is curable.

(6.) There is no evidence to show that sclerosis, once existing in the spinal cord, has ever been removed.

(7.) Those cases of so-called locomotor ataxia which have been cured are simply cases of spinal congestion, more profound in the posterior half at the cord.

DR. WM. A HAMMOND related a remarkable case of cure of apparent locomotor ataxia, with most extreme lancinating pains and loss of tendon reflex, which was entirely cured within a month. As there was a suspicion of syphilis, anti-syphilitic treatment was at first adopted; but this not affording any relief, nitrate of silver was substituted for it, with codeia at night to secure sleep. He did not know how to explain this case except on the hypothesis of congestion.

DR. S. G. WEBBER said that he had reported two or three cases in which tendon reflex was restored in patients who had had all the symptoms of locomotor ataxia. He also mentioned one case of supposed ataxia, reported by Déjerine, in which the autopsy showed that the real pathological condition was multiple neuritis. He was disposed to doubt whether hyperæmia of the columns of the cord could continue for weeks and months without giving rise to organic changes, and thought that such a condition was, at all events, not yet proven. The discussion was also participated in by Drs. Rockwell, Corning, Massey, Mills, Bannister, Birdsall, and Bartholow, and the latter stated that he believed that the process of sclerosis in locomotor ataxia could be arrested by chloride of gold, although it had no effect in restoring parts that had already been lost.

DR. S. G. WEBBER, of Boston, read a paper on

MULTIPLE NEURITIS.

Having referred to the cases that had been reported by various authors and the bibliography of the subject, he said that up to this time he had found the records of six cases without autopsies and twelve cases with autopsies. He then proceeded to give the detailed histories of four cases which had been under his own care, two of which proved fatal. In one of these the patient

was nearly moribund when admitted to the hospital and died within two days, and the other lived for seventeen days after admission. Specimens from the latter exhibiting degeneration of nerve tissue were shown under the microscope. During the autumn and winter of 1883 and 1884, no less then eighteen cases of multiple neuritis entered the Boston City Hospital, fourteen of which came under his own observation. He also saw one case in private practice, and a second case in which the diagnosis was somewhat doubtful between this disease and infantile paralysis. Of the nineteen undoubted cases ten were males and nine females. There were three deaths in all. Disturbance of sensation was one of the most constant and prominent symptoms, and the pain, differing greatly in severity in different cases, was variously described as aching, boring, shooting, and burning. There was also, as a rule, marked hyperæsthesia of the skin and tenderness of the muscles as well as over the nerve-trunks. Motion was early disturbed. At first there was stiffness, and afterwards paralysis, more or less complete. The limbs became contracted, semi-flexed, and sometimes the contractions were extreme. The electrical reactions of the muscles and nerves showed the changes due to their respective degeneration. The various tendon reflexes were generally absent, while the cutaneous reflexes were less disturbed. The temperature and pulse were rather elevated in the earlier stages of the disease, and in the two fatal cases throughout the period when they were under observation. There was atrophy of the muscles, and in some patients great general wasting of tissue. In others there was œdema of the limbs and even of the face, and some had excessive sweating, which made the cases simulate rheumatism. The disease began in the legs, and was sometimes confined to them.

Now that the peculiar symptoms of multiple neuritis had been clearly marked out, the diagnosis was not difficult in well-marked cases, but in light cases might be difficult. Dr. Webber then pointed out the differential diagnosis between it and anterior poliomyelitis, progressive muscular atrophy, lead paralysis, rheumatic fever, and spinal meningitis. Having mentioned that Scheube had found neuritis in every case of the disease known in Japan as kakke, which he believed to be due to a specific poison, and that recently Dr. J. B. de Lacorda had claimed to have discovered the bacillus of beri-beri, he went on to say that the pathological process in multiple neuritis was generally believed to be an inflammation of the nerves, although Erb had suggested that the phenomena noted might be dependent on central disturbances. He then described the degenerative changes in the nerves, and also referred to the pathological conditions found by Gombault in rabbits, in which he produced neuritis artificially. His conclusion was that, considering the changes found about the annular constrictions, it was reasonable to consider the disease a neuritis, not dependent upon changes in the spinal cord. In most cases the patients recovered more or less completely, but recovery was very slow in severe cases.

He was not sure, he said, that any treatment shortened the attack. Salicylic acid seemed to cut short the pain in some instances, and when it returned it was not quite so severe. It was necessary to give morphia to relieve pain. A four or five per cent. solution of carbolic acid applied on cloths to the painful limbs was of decided advantage. Lister's seemed to be of advantage in two or three instances, especially in a case where the hyperæsthesia was very persistent. He thought it well to try to avoid or diminish the extent of the contractions by gentle extension or position of the limbs, a sand-bag to rest the feet against, etc., as the contractions were difficult to overcome. To do so required a persevering use of massage, extension, and electricity.

DR. ROCKWELL said that in a case of neuritis that he had had, the repeated application of the actual cautery to sensitive points all over the body afforded very marked relief; but he could not say whether it had any ultimate effect upon the course of the disease, as the patient passed from out of his observation.

DR. R. W. AMIDON, of New York, presented the brain taken from a patient suffering from Word-Deafness and Blindness, without Paralysis, and DR. ROBERTS BARTHELOW, of Philadelphia, read a note on

SOME USES OF THE CHLORIDE OF GOLD AND SODIUM IN NERVOUS AFFECTIONS.

He preferred the double chloride of gold, on account of its much greater diffusibility than the simple chloride, and used it in doses of one twentieth of a grain two or three times a day. It was an alterant, or, as this class of agents were now more properly called, a promoter of tissue metamorphosis. It was also a good tonic, and increased the number of red blood globules; but its chief effect was upon connective tissue. Hence, in pathological conditions in which the connective tissue was involved, it was likely to be of service. In sclerosis of the posterior columns of the spinal cord he did not claim that the patient could be restored to the *status in quo*, but his experience with it had been such as to convince him that by means of it the disease could often be arrested. Its effect in fibroid kidney was sometimes remarkable. He had also found it of benefit in asthma, laryngismus stridulus, and other forms of spasm, in sexual debility, and in hypochondriasis.

THIRD DAY. AFTERNOON SESSION.

COMMITTEE ON ENCEPHALIC NOMENCLATURE.

The following resolution, prepared by DR. WILDER, was adopted: "*Resolved*, that there be appointed by the chair a committee of five on macroscopic encephalic nomenclature, with instructions to report at the next meeting a list of such terms as in their judgment may be properly recommended for use;" and the President appointed the committee as follows: E. C. Spitzka, Chairman; Burt G. Wilder, T. A. McBride, W. A. Birdsall, and L. C. Gray. On motion of Dr. Bartholow, the other two resolutions of Dr. Wilder were referred to this committee.

The President, DR. ISAAC OTT, of Easton, Penn., read a paper on

THE RELATIONS BETWEEN INJURIES OF THE SPINAL CORD AND THE EXCRETION OF CARBONIC ANHYDRIDE.

By means of Arsonval's calorimeter and Voit's respiration-apparatus, he had made a series of experiments upon the lower animals, and had arrived at the conclusion that injuries of the cord produce, as a rule, an increase of the excretion of carbonic anhydride. It did not seem to make any difference whether the gray or white matter, or both together, were injured; the increase ensued just the same. Although the calo-

rimeter was kept at 100° F., in only two cases out of seven did he see any increase of temperature. In all the others it fell below normal.

After some discussion of this paper. Dr. G. L. WALTON, of Boston, read a paper entitled

A CONTRIBUTION TO THE STUDY OF HYSTERIA BEARING ON THE QUESTION OF OÖPHORECTOMY.

We should limit the question of oöphorectomy, he said, to those cases in which the hysteria is secondary to abdominal trouble, and carefully exclude those in which the menstrual irregularities and ovarian tenderness are secondary to the hysteria. The most plausible explanation of hysterical hemianæsthesia (common after ovarian irritation) is that of spasmodic contraction of the cortical blood-vessels of the brain, suspending the function of the cortical nerve cells through lack of nutritive fluid. This theory explains best, for example, the rapid onset and disappearance of the symptoms; for we know that a thought is sufficient stimulus, and one instant sufficient time to cause the most extreme changes in the calibre of blood-vessels, as is instanced in the blush on the one hand and the pallor of fear on the other. That such sudden changes take place in the brain as well as the integument is shown by the phenomenon of fainting, in which the cerebral functions are entirely suspended, presumably through lack of blood. The transfer of anæsthesia from side to side with succeeding oscillations is suggestive of the ebb and flow of a fluid. That vaso-motor irregularities are common in hysterical patients in other parts of the body as well as the brain is evidenced by the frequency of chills, flushes, and ischæmia, sudden swelling of the joints, etc. Weight is thrown in favor of this theory by the case published in a paper by the author on Oöphorectomy in Hysteria, in the *Boston Medical and Surgical Journal* of June 5, 1884. In this case right-sided hemianæsthesia coincided with left-sided angio-spasmodic migraine and left-sided intermittent retinal ischæmia (the blood-vessels of the right eye being normal). The only explanation to be offered was that spasm of blood-vessels by implicating the membranes caused the pain, by extending into the cortex the hemianæsthesia of the opposite side, and by extending to the eye evidenced itself in the abnormal contractility of the retinal vessels of the same side. The starting-point in this case was pelvic disease, probably by irritation of the sympathetic nerves supplying the ovarian region. In favoring this theory, he said, we are dealing with a tangible phenomenon of which we have constant examples, and cannot be accused of a flight of imagination. Dr. Walton has failed to produce "transfer" in hysteria secondary to pelvic disturbance, but has observed it frequently in cases of constitutional hysteria. This is probably because the unilateral spasm is kept up in the one case by the organic trouble, while in the other the sympathetic irritability is alike on both sides of the brain, so that while the vessels are contracting on one side they are dilating on the other. In conclusion, the case of Miss A. (of which the principal points of interest were given in the paper already referred to) was reported in detail. It was operated on by Dr. Barss; the removal of both ovaries being followed by marked improvement in hysterical convulsions and hemianæsthesia of thirteen years' standing.

A lengthy discussion followed the paper, which was participated in by Drs. Spitzka, Mills, Putnam, Rockwell, and (by invitation) Mary Putnam Jacobi. In closing the discussion Dr. Walton said that hardly any one could be more conservative than himself in regard to the operation, except some one who was opposed to it under any circumstances whatever, since it was only in cases in which the hysterical symptoms were obviously secondary to pelvic disease that he would recommend it. One cause why the relief had not been greater in his case was, he thought, that the Fallopian tubes were allowed to remain. Tait had repeatedly found that menstruation was very apt to continue unless the tubes, as well as the ovaries, were removed, although this was not the case here. Still, but a comparatively short time had as yet elapsed since the operation, and he trusted that the improvement would gradually become more marked. He agreed with those who believed that hysteria was almost always of central origin, and that it was only in a comparatively few cases that it was dependent on uterine or ovarian conditions.

DR. J. J. PUTNAM read a paper upon

THE MEDICO-LEGAL SIGNIFICANCE OF TYPICAL SO-CALLED HYSTERICAL SYMPTOMS OCCURRING IN MEN AFTER RAILWAY AND OTHER INJURIES.

When a claim is made for damages after concussion-accidents which leave no objective sign of disease, the first point to be settled is with regard to the claimant's trustworthiness.

The discovery of typical symptoms of hemianæsthesia, affecting the skin and special senses (field of vision, color-sense, etc.), should go far towards establishing veracity, because these symptoms are not such as the patient could simulate without careful preliminary study, while, if taken together, they form a distinct picture of hysteria. The reader had reason to think that these symptoms are by no means rare, and reported one well-marked case.

The question then arises whether the diagnosis of hysteria should be put forward by the plaintiff or not. The reader thought it often advisable to do this, in order that the medical aspects of the case should be discussed on their true merits.

Hysteria is sometimes a trifling, but sometimes a very serious, disease, and it is well that lawyers and juries should realize that fact.

DR. DANA said that he fully recognized the difficulties to which Dr. Putnam had alluded. A great deal of confusion had been thrown on the matter by Erichsen, and he thought that it would be of great benefit if some authoritative statement could be made of the relative value of Erichsen's and Page's opposing views. There was one point to which Dr. Putnam had not referred. Hysteria was, no doubt, a serious disease, but the question arose in every case such as he had described whether the symptoms were really due to the accident, or were excited by the hope of reward. He had not found the existence of hemianæsthesia in males, as Dr. Putnam had. In conclusion, he mentioned one objective symptom which he thought might be of some value, and that was electric resistance, as tested by the galvanometer.

DR. PUTNAM said that he believed that this whole subject ought to be reopened from a different point of view than that from which it was now regarded. The slightness of the injury did not seem to be of much consequence. In his own case the injury had been slight, and yet from the very first day the patient had been seriously affected. No thought of obtaining dam-

ages, he believed, could have had any effect in originating the hysterical trouble in this instance. He advised that sensibility should be tested in all respects for hemianæsthesia, the special senses as well as the skin. Having referred to the question of atrophy in this connection, he said that he agreed with Dr. Dana that electrical resistance was an important point.

DOUBLE HEMIPLEGIA.

DR. SARAH J. MCNUTT, of New York, read the report of a case (with specimen) of double hemiplegia in a child, in which there was extensive atrophy of the cerebral cortex, the disease being pronounced by Dr. William H. Welch to be sclerosis of the greater part of the motor tract, with degeneration of the pyramidal tracts.

THIRD DAY. EVENING SESSION.

DR. W. A. BIRDSALL, of New York, read a paper on

OPHTHALMOPLEGIA EXTERNA PROGRESSIVA,

in which he reported two cases of slowly progressive paresis of all the external muscles of both eyes, producing ptosis and nearly complete immobility of the eyeballs, with complete preservation of the functions of the internal ocular muscles, accommodation being normal, and reaction of the iris to light and accommodation movements also normal. There was no heredity and no suspicion of syphilis. Slow improvement occurred in one case under large doses of iodide of potassium, and in the other under the use of the same drug and faradization of the eyes. Dr. Birdsall believed the affection to be one of the nuclei of the sixth, fourth, and parts of the third nerves, which supply the external ocular muscles, these parts representing an associated system. Degeneration within this system of associated muscles, nerve tracts and centres, similar to the degeneration of progressive muscular atrophy and of labio-glosso-pharyngeal paralysis, as suggested by Hutchinson in similar cases, appeared to be the most consistent theory of the pathology.

LOCOMOTOR ATAXIA AND SYPHILIS.

Some statistics in reference to the relative frequency of locomotor ataxia in syphilitics, which were sent by Dr. E. C. Seguin (who was confined to the house by illness), were read by DR. BIRDSALL. There were seventy-two cases in all, and of these twenty-two, or 30 per cent., had had chancre, and sixteen, or 22.2 per cent., chancre followed by secondary symptoms. In fourteen cases, or 19.8 per cent., there had been neither chancre nor secondary symptoms, and in twenty, or 28 per cent., there was no mention made of syphilis. Statistics and remarks upon them were also offered by Drs. Birdsall, Spitzka, Rockwell, Putnam, and Webber.

DR. C. L. DANA, of New York, read a paper entitled

FOLIE DU DOUTE AND MYSOPHOBIA.

He referred to the history of *folie du doute*, or the "doubting madness," in which the patient was harassed with a constant desire to question, speculate, and refine over details. His mind was never settled, but was in a condition of "pruritus." It was a psychopathic symptom, which indicated that the patient was a monomaniac, and truly insane, or only hypochondriacal, or profoundly neurasthenic and hysterical. Mysophobia, or fear of contagion, was a symptom indicating probably a similar condition. *Folie du doute* had been divided by Ball into several varieties, such as the suspicious, the calculating, the timid, and, finally, the tactile, and mysophobia had been classed as the tactile form of *folie du doute*. This classification was, perhaps, open to criticism, but Dr. Dana was inclined to think it was correct. He then related in detail two cases: one a typical one of *folie du doute*, as described by Fabret, Ball, and others, and the second a case of mysophobia, as first described by Hammond.

DR. SPITZKA said that the class of patients described by Dr. Dana, although of perfectly sound mind in all other respects, were suffering from *bona fide* insanity. In males the principal cause was masturbation.

OTHER PAPERS.

DR. G. BELTON MASSEY, of Philadelphia, read a paper entitled A Case of Sudden Loss of Vision following Anæsthesia of the Fifth Nerve, with Remarks on the Modifying Effect of Anæsthesia on the Galvano-Reactions of the Special Senses.

Among the other papers presented were one by Dr. George W. Jacoby, of New York, on Cerebro-Spinal Saturnism, and a communication from Dr. John J. Mann, of Newport, R. I., accompanied with seven photographs taken for the purpose of showing the impossibility of mistaking the auditory for the trigeminal region in the medulla oblongata of reptiles. A memorial of the late Dr. George M. Beard was also presented by Dr. Dana, who, with Dr. C. K. Mills, of Philadelphia, was last year appointed on a committee for that purpose.

During the meeting Dr. Danillo, of St. Petersburg, and Dr. Auguste Forel, Professor of Psychiatry in the University of Zurich, Switzerland, were elected associate members of the Association.

ANNUAL MEETING OF THE CENSORS OF THE MASSACHUSETTS MEDICAL SOCIETY.

ALBERT N. BLODGETT, M. D., CLERK.

THE annual meeting of the Censors of the Massachusetts Medical Society was held at 19 Boylston Place, June 10, 1884. There was a fair representation of the District Societies by delegates. DR. C. HOWE, of Bristol North Society, was elected chairman. The records of the last annual meeting were read and approved.

THE METHOD AND STANDARD OF EXAMINATION OF CANDIDATES BY THE SEVERAL BOARDS OF CENSORS.

The clerk announced that the committee which had served the Society for the past two years had prepared a final report, which had been forwarded to the meeting, as the chairman of the committee had been unavoidably detained from the meeting. The clerk was requested to read the report, which was as follows: —

The committee appointed at the Conference of Censors, held June 11, 1883, "for the purpose of watching the results of their action during the past year," respectfully submits the following report: —

In April a circular, a copy of which is herewith submitted, was mailed to the secretary of each District Society. Answers have been received from fourteen districts, namely: Barnstable, Berkshire, Bristol North, Bristol South, Essex North, Essex South, Hampden, Hampshire, Middlesex East, Middlesex North, Middlesex South, Norfolk, Plymouth, and Suffolk. No re-

sponse has come from Franklin, Worcester, Worcester North.

The answers are appended to this report, together with copies of the questions used in written examinations in several districts.

It appears that written examinations are used wholly or in part in nine of the districts heard from, namely: Barnstable, Bristol North, Essex South, Hampden, Middlesex East, Middlesex North, Middlesex South, Plymouth, Suffolk, and Worcester North. The examinations are wholly oral in five districts, namely, Berkshire, Bristol South, Essex North, Hampshire, and Norfolk. It will be remembered that the By-laws of the Society require that a part of the examination shall be in writing. For the committee,

J. T. G. NICHOLS, *Chairman.*

(Circular.)

MASSACHUSETTS MEDICAL SOCIETY.

DR. ——

Secretary —— ——, *District Society.*

The committee appointed at the conference of Censors, held June 11, 1883, respectfully asks an early answer to this question: What, if any, changes have been made by your Board of Censors during the past year in the method of examining candidates for admission to the Society? Will you forward a copy of questions used in written examinations, if such have been held?

The committee urges your Board to send delegates to the next conference of Censors, reminding you that, as its name implies, it is a meeting for discussion only.

J. T. G. NICHOLS, Middlesex South.
GEORGE C. MCCLEAN, Hampden.
BENJ. H. HARTWELL, Worcester North.
Committee.

(Replies.)

BARNSTABLE DISTRICT.

YARMOUTH PORT, MASS., *May* 1, 1884.

DR. NICHOLS:

Dear Sir, — In reply to your circular I would say that our Board of Censors (Barnstable District) have made no change in their method of examining candidates for admission to the Society, for if a man can pass the Censors in *this* District I think he could in *any*. Each examiner asks as many questions as he chooses, one half of which are in writing. Every branch is touched upon, and a man has to be well posted in order to pass the Board of Censors for Barnstable District.

Very respectfully yours, S. F. HASKINS, M. D.,
Secretary Barnstable District Medical Society.

YARMOUTH PORT, MASS., *May* 9, 1884.

DEAR DOCTOR, — I have n't a copy of any questions used by the Censors in their examinations, as we have written them at the time of making the examination, and never have preserved them.

We always give the candidate about twelve written questions and as many oral ones as we may please.

Very truly yours, S. F. HASKINS.

DR. J. T. G. NICHOLS, Cambridge.

BERKSHIRE DISTRICT.

PITTSFIELD, MASS., *April* 27, 1884.

DR. J. T. G. NICHOLS:

Dear Sir, — In reply to your letter of last week I would say that no changes have been made in the method of examining candidates for admission to the Society.

The examination by the Berkshire Board of Censors has always been an oral one. I will present your letter to the Society at its annual meeting on Wednesday.

Yours very truly, HENRY COLT, JR.,
Secretary Berkshire District Medical Society.

BRISTOL NORTH DISTRICT.

TAUNTON, *May* 20, 1884.

DEAR DOCTOR, — I hope you will pardon the delay in answering your note. Absence from home prevented its earlier recognition.

There has been no change made by the Board of Censors in their method of examining candidates. The examinations are both written and oral. I forward, at your request, a copy of the written questions used at the last meeting of the Board of Censors. Yours very truly, E. F. GALLIGAN,
Secretary.

TO DR. J. T. G NICHOLS, Cambridge, Mass

Materia Medica and Therapeutics.

(1.) Properties, preparations, doses, and uses of *aconite.* (2.) Of digitalis. (3.) Of salicin.

General and Medical Chemistry.

(1.) Neutral salts and how formed. (2.) How to detect sugar in the urine.

Theory and Practice.

Case of true croup. Case of spasmodic croup. Pathology of each. Differential diagnosis, prognosis, and treatment of each.

Midwifery.

Describe a case of normal labor. Case of puerperal fever, or septicæmia; pathology, symptoms, diagnosis, prognosis, and treatment.

Prescription.

Write a prescription in Latin for a cough mixture containing sulphate of morphine and syrup of squills.

Anatomy and Physiology.

Name the bones of the head. Name the muscles of the arm. What forms the circle of Willis? What is the function of bile? What action does saliva have on starch? Give the specific gravity and reaction of gastric juice, and what does it digest?

Surgery.

Fracture of femur at its upper third. Different kinds. Differential diagnosis. What splints and apparatus to be used in each form of fracture.

BRISTOL SOUTH DISTRICT.

NEW BEDFORD, *May* 20, 1884.

DR. J. T. G. NICHOLS:

Dear Sir, — We have made no changes in our method of examining candidates for admission to the Society. Our examinations have been entirely oral. Very truly yours,
A. MARTIN PIERCE,
Secretary Bristol South District Medical Society.

ESSEX NORTH DISTRICT.

NEWBURYPORT, *April* 29, 1884.

DEAR SIR, — There has been no change in the method of examination of candidates for admission to the Society by the Board of Censors of the Essex North District Medical Society. We do not have written examinations.

Yours respectfully, GEORGE W. SNOW,
Secretary.

ESSEX SOUTH DISTRICT.

11 FRANKLIN STREET, LYNN, *May* 4, 1884.

DR. J. T. G. NICHOLS, Chairman of Committee, etc.:

Dear Sir, — No special change has been made by the Censors of the Essex South District in the method of examining candidates for admission to the Society, and no forms of the questions used in the written examination are accessible.

I shall be glad to lay your letter before the Board of Censors of this District, and have no doubt that delegates will be sent to the next conference of Censors.

Please excuse my delay in answering, and believe me,
Very sincerely yours, C. C. SHELDON.

HAMPDEN DISTRICT.

SPRINGFIELD, MASS., *May* 7, 1884.

DEAR DOCTOR, — Your circular was duly received. Please find herewith a copy of the examination held last October, which is a fair sample of the work of our Censors' Board. The marking was on a scale of 100, and fifty per cent. required to pass. The answers of each candidate were read by the secretary to the Censors, question by question, and each Censor marked each upon its merits, at the end finding the general average, which was handed to the secretary, who alone knew whose answers were being marked. These averages, added and divided by the number of Censors, gave the final result, which passed the candidate if it reached fifty per cent.

I am thus explicit because a charge was made at the Censors' convention last year by one of our own Board that the Censors of Hampden had been guilty of "injustice" in their examina-

tions. The gentleman making this charge was newly elected a Censor, and had never acted as such, or looked at the records; but a personal friend of his and a fellow-member in a local medical club had unfortunately first failed to pass our Board, and hence his feeling, so strongly expressed.

At a subsequent meeting the questions upon which "injustice" was done were read to this Censor, one by one, and he failed to object to a single question as improper or too difficult; and since that time he has worked in perfect harmony with the Board, and assisted in the preparation of the paper I inclose, which will compare favorably with that printed from our district last year.

The candidate referred to above said he felt at the time that he did not do himself justice, and showed his excellent good sense by applying again, and was admitted. Our critical Censor is appointed delegate to your convention this year, and doubtless you will hear from him there. The general opinion in this district seems to uphold the effort for high standard, and I think you may count on us to aid in any measure proposed toward this end. Very truly yours,

GEORGE C. McCLEAN,
Secretary Hampden District.

DR. J. T. G. NICHOLS, Chairman Committee Censors.

Anatomy.

(1.) Over what areas would you percuss the lungs, heart, liver, spleen, stomach? (2.) What organs suffer most in dilatation of the heart? (3.) In what direction would you cut the internal ring in inguinal hernia? The crural ring in femoral hernia? Why?

Physiology and Chemistry.

(4.) Give tests for albumen and glucose. (5.) Describe the arrangement of gray and white substances of the spinal cord, their functions, and mention some of the results of paraplegia; of hemiplegia. (6.) Describe the digestive process, and how affected by acids and alkalies.

Materia Medica and Therapeutics.

(7.) Give the symptoms and treatment of poisoning by opium. (8.) Mention, and give the dose, of three principal mineral cathartics. Of three vegetable cathartics. (9.) Give the uses of ipecac, and write prescription containing it.

Theory and Practice.

(10.) What are a few of the more common sequelæ of scarlatina? (11.) Give briefly the clinical history, diagnosis, and treatment of peritonitis. (12.) What would be the appearance of the liver in a man who had died of cirrhosis of that organ?

Surgery.

(13.) Strangulated oblique inguinal hernia: Describe the symptoms and treatment. (14.) Traumatic gangrene: State in what sort of cases it is likely to happen, and describe the treatment. (15.) Tracheotomy: When and how would you perform it?

Obstetrics.

(16.) Give the mechanical conditions and the changes which take place in a normal labor. (17.) What are the causes of ante- and post-partum hæmorrhage, and the treatment of each? (18.) When and how would you diagnose a face anterior? What causes this anterior position? Treatment?

Please number the answers, and be as brief and concise as possible.

HAMPSHIRE DISTRICT.

NORTHAMPTON, MASS., *April* 29, 1884.

DR. J. T. G. NICHOLS:

Dear Sir, — Your letter of no date in reference to Censors is at hand. There has been no change in the method of examining candidates. We have no written examinations. Practically the responsibilities of the Censors here prove to be light, and I am not aware of any special interest in the subject.

Yours truly, CHARLES W. COOPER,
Secretary Hampshire District Society.

MIDDLESEX EAST DISTRICT.

READING, *May* 15, 1884.

DR. NICHOLS:

Dear Sir, — In reply to your circular of inquiry I will say: Our Board of Censors has made no change in its method of examining candidates for Fellowship. Our Board will send delegates to the next conference of Censors. I herewith inclose a list of questions used at our last examinations, yesterday.

Yours respectfully, GEO. E. PUTNEY,
Secretary Middlesex East District.

(1.) What is probably the most effective emetic, given hypodermically? (2.) Describe, briefly, nux vomica and give its physiological action. (3.) Give treatment of pneumonia. (4.) Pathology of acute rheumatism. (5.) What is hæmatocele? (6.) How many teeth in temporary set? How many teeth in permanent set? (7.) Name the branches of the aorta. (8.) A bullet wound through the palm. Its complications, dangers, and treatment. (9.) Dislocated hip, with fracture of femur at upper third. Treatment. (10.) When may it be necessary to make an artificial anus? Describe the operation. (11.) Sterno-cleido-mastoid muscle. Origin and insertion. (12.) Describe the signs of pregnancy. (13.) What do you think of carbolized vaginal injection after parturition? (14.) Describe two tests for arsen. acid. What is the best antidote for as. acid? (15.) What is the difference between carbonic acid and carbonic oxide? (16.) What is the composition of atmospheric air?

MIDDLESEX NORTH DISTRICT.

LOWELL, MASS., *May* 22, 1884.

DR. NICHOLS:

Dear Sir, — At the regular meeting of the Censors of the Middlesex North held on the 30th ult., Dr. T. Pierpont Shaw was chosen a delegate to attend the annual meeting of Censors for the State.

No changes have been made during the year as to methods of examination. I send herewith questions as you request.

We always have written and oral examinations.

Yours truly, GEO. C. OSGOOD,
Secretary Middlesex North.

Anatomy.

Name and describe (1.) The bones of the fore-arm. (2.) The bones of the ankle-joint. (3.) The anterior humeral muscles. (4.) The vessels which directly enter into or issue from the heart. Describe (5.) The knee-joint. (6.) The femoral artery. (7.) The relative position and structure of the liver. (8.) The peritonæum. (9.) The origin and distribution of the facial nerve. (10.) The contents of the left lumbar region.

Pathological Anatomy.

Describe (1.) The liver in cirrhosis. (2.) The kidney in chronic parenchymatous nephritis. (3.) Round ulcer of stomach. (4.) Possible lesions of typhoid fever. (5.) An embolus and its possible causes and effects.

Physiology.

(1.) Describe the process of deglutition. (2.) Composition and digestive action of (1) gastric juice, (2) bile. (3.) Describe the action of the diaphragm. (4.) Name the principal secretions. (5.) The constituents of blood and their relative proportion. (6.) What is the function of a motor nerve? of a sensory nerve? Give illustration of each kind. (7.) Describe the innervation of the heart. (8.) Source and method of production of animal heat. (9.) What are the lymphatics? Explain their function. (10.) What changes take place in the circulation of the fœtus at birth?

Chemistry.

(1.) What substances are *always* found in normal urine? (2.) Give two differenttests for albumen in urine, and state what precautions are necessary in each. (3.) Given a specimen of urine containing albumen, what further information is needful as a guide to diagnosis? (4.) How test for sugar in urine? (5.) Sources and symptoms of arsenic poisoning. (6.) What substances are incompatible with iodide of potassium? (7.) What circumstances favor the solution of lead in water? (8.) Write the chemical formula for corrosive sublimate and for calomel.

Surgery.

(1.) How reduce a dislocation of the shoulder? (2.) Treatment of erysipelas. (3.) Treatment of mammary abscess. (4.) Describe the proper method of passing a catheter into the male bladder, what difficulties may be met, and how to overcome them. (5.) Describe tracheotomy. (6.) Causes and treatment of tetanus. (7.) Treatment of fracture of rib. (8.) Describe hæmorrhoids and their treatment.

Materia Medica and Therapeutics.

(1.) Name two useful preparations and state therapeutic action and doses of opium, iron, digitalis, mercury, ipecac. (2.) Name three cathartics and dose of each. (3.) Name the principal diuretics, their sources, and their common preparations. (4.) Into what classes may expectorants be divided? Mention one of each class and state its appropriate use. (5.) Write a

prescription for acute pneumonia, and state in what stage of the disease it would be applicable for use. (6.) Name the leading hypnotics, and state the indications and the contra-indications for the use of each. (7.) Antidotes for opium, phosphorus, arsenic, and method of their administration. (8.) Write a prescription for a child of one year with gastro-enteritis. (9.) In what form and dose should opium and belladonna be used subcutaneously. (10.) The physiological action of alcohol.

Theory and Practice.

(1.) Symptoms and differential diagnosis of acute lobar pneumonia. (2.) Causes of chronic interstitial nephritis. (3.) Causes and treatment of typhoid fever and all its ordinary complications. (4.) In what diseases does jaundice appear, and what is its significance? (5.) What are the different forms of nephritis, and what is their relative prognosis? (6.) Treatment of scarlatina and of its sequelæ. (7.) In what ways may death occur from diphtheria? (8.) What are the physical signs of mitral insufficiency? of acute pleurisy? (9.) Symptoms and treatment of peritonitis. (10.) Symptoms and treatment of chorea.

Obstetrics.

(1.) Signs of pregnancy at the end of fourth month. (2.) Describe the mechanism of a normal labor, and state what assistance should be given, and when and how. (3.) Treatment of placenta prævia. (4.) When and why use ergot in labor? (5.) Management of a face presentation (6.) Management of a hand presentation. (7.) Treatment of post-partum hæmorrhage. (8.) Causes and treatment of the albuminuria of pregnancy.

Hygiene.

(1.) How many cubic feet of air space should be provided for each adult in his sleeping room? (2.) What diseases may be taken through the medium of the drinking water? (3.) What special precautions should be taken against the spread of typhoid fever, of small-pox, and of scarlet-fever? (4.) What is the meaning of endemic as applied to disease? (5.) What diseases become at times epidemic in New England?

MIDDLESEX SOUTH DISTRICT.

LIST OF QUESTIONS FOR THE APRIL EXAMINATION.

(1.) Describe the pectoralis major muscle. (2.) How is Scarpa's triangle bounded? What are its contents and their relation to each other? (3.) What is the average amount of urine excreted in twenty-four hours? (4.) What are the functions of the red corpuscles of the blood? (5.) Explain the difference between fatty degeneration and fatty infiltration. (6.) What lesion of the heart is found accompanying interstitial nephritis? (7.) Differential diagnoses of gout and rheumatism. (8.) Asthma: varieties, diagnosis, treatment. (9.) Widow, forty, generally well, has had malaise for several days, suddenly attacked with chilliness, but no distinct rigor; pain in head, limbs, and back; face flushed, skin hot and dry. Pulse 118; respiration 22; temperature 104° F. Tonsils red, swollen, and showing small white spots here and there. Diagnosis? Reasons? (10.) A single woman, twenty-one, generally well; an attack of pain in the abdomen coming on suddenly, most severe in left lumbar and iliac regions; remittent at first; in an hour became constant and very severe, with cold extremities and vomiting, continued about three hours and ceased suddenly; no fever. Diagnosis? (11.) Opium, from what derived, most important preparations and doses. (12.) Same of belladonna. (13.) Physiological action and therapeutic uses of digitalis, in small, large, and poisonous doses, and antidotes. (14.) Same of chloral. (15.) Inflammation, acute and chronic. Local signs, constitutional signs, treatment. (16.) Fracture of femur. (17.) Symptoms and treatment of a case of placenta prævia. (18.) Define an element. (19.) From what substance is metallic mercury obtained? (20.) A case of diphtheria occurs in a family where there are other children, what would you do to prevent the disease from spreading before and after the termination of the case?

NORFOLK DISTRICT.

ROXBURY, BOSTON, MASS., *May* 9, 1884.

DR. J. T. G. NICHOLS, Chairman of Committee, etc.:

Dear Sir, — Your circular received. After communicating with the chairman of this District Board of Censors I would reply: —

There have been no material changes made in the method of examining candidates. Each examiner is assigned certain subjects, upon which he always examines. The examination is oral, not written. Respectfully,

GEORGE D. TOWNSHEND,
Secretary Norfolk District Medical Society.

P. S. Will notify you of the appointment of delegates to the Censors' conference when the new Board of Censors for this district makes said appointments.

Please inform me the date of the meeting of the conference, and oblige G. D. T.

PLYMOUTH DISTRICT.

BROCKTON, *May* 2, 1884.

DEAR DOCTOR, — In regard to examinations of candidates for membership to the Massachusetts Medical Society in this *district* (*Plymouth*) during the past year the method was the same as that of the previous few years. The questions in all branches have been practical, but perhaps not always touching upon things commonly met with, nevertheless touching upon such things or subjects as it is necessary to know. I have not a list of questions used in the examinations, as we never have been accustomed to copy them into the record of the doings of the Society. The examinations have all been written ones, and if there were more candidates than one at the same time they had the same questions, but were placed in separate rooms.

I am sorry that I could not give you a copy of questions.

Yours respectfully, J. E. BACON,
Secretary for Plymouth District.

SUFFOLK DISTRICT.

19 EXETER STREET, BOSTON, *April* 27, 1884.

DR. J. T. G. NICHOLS:

Dear Sir, — There have been no changes in the method of examining candidates for admission to the Society during the past year.

I inclose copies of questions used in examinations.

Yours very truly, H. C. HAVEN,
Secretary Suffolk Censors.

P. S. I presume you only wish papers of last year; I can furnish others if desired.

Massachusetts Medical Society. Censors' Examination, September 27, 1883.

(1.) The relations of the vessels, muscles, and tendons in the palm of the hand. (2.) Differential diagnosis between fracture and dislocation of the hip-joint, and between hip-joint disease and malignant tumor of the upper part of the femur. (3.) What is the function of the liver? What is reflex action? What changes take place in the blood in the pulmonary circulation? (4.) What is apoplexy? What and where are the characteristic lesions of typhoid fever? What is erysipelas? (5.) Write a prescription, with directions and dose of each, for (*a*) a cathartic; (*b*) a tonic; (*c*) a sedative; (*d*) a stimulant; (*e*) a diaphoretic; (*f*) a derivative; (*g*) an emmenagogue. (6.) Give the dose of (*a*) arsenic; (*b*) mercury; (*c*) iodine; (*d*) iron; (*e*) lead; (*f*) bismuth; specifying the most desirable forms of each, with directions for administration. (7.) Differential diagnosis between parenchymatous and interstitial nephritis. (8.) Describe a case of cerebro-spinal meningitis. (9.) In the female pelvis which is the smallest diameter at the basin? At the outlet? (10.) When would you give ergot?

[Two hours allowed for the written examination.]

Massachusetts Medical Society. Censors' Examination, February 21, 1884.

(1.) Contents of the abdomen; their relations to the peritonæum and to each other. (2.) Hernia: varieties; causes; appearance; treatment. (3.) Normal constituents of the urine. Functions of the bile and pancreatic fluid. (4.) Causes of valvular disease of the heart. Pathological appearances in typhoid fever. (5.) Describe physiological action of ether; of chloroform; of nitrous oxide; the dangers attending each, and their treatment. (6.) State the symptoms induced by mercury; by lead; by phosphorus; with treatment. (7.) Describe a case of typhoid fever, with the treatment of any complications which you may think of arising in the course of the disease. (8.) The diagnosis and treatment of diphtheria. (9.) How early and by what signs can pregnancy in a primipara be detected with certainty? (10.) Which are the two longest diameters of the fœtal head?

[Examination limited to two hours.]

WORCESTER NORTH DISTRICT.

FITCHBURG, MASS., *June* 9, 1884.

DR. NICHOLS:

Dear Sir, — The examination of candidates for the past year has been by written questions and answers. I send all those that I have happened to preserve.

Give origin and attachment of psoas magnus muscle; also sartorius muscle. What changes take place in the air as it is inhaled and exhaled from the lungs, and what changes take place in the blood by respiration? Give formula for nitric acid. What is the only fluid metal? Give the chemical composition of castile soap. Give chemical name and formula for plaster of Paris. Give signs and duration of pregnancy. Describe a natural labor. What are the ordinary dangers of labor? When, if ever, would you give ergot? When would you use the forceps? Give difference between unavoidable and accidental hæmorrhage, and treatment of each. Give the symptoms of compression of the brain; also concussion of the brain. Treatment of each. The difference between phimosis and paraphimosis, and treatment of each. How would you treat a fracture of the olecranon? How reduce a dislocation of the humerus? Name points in the differential diagnosis of croupous and catarrhal pneumonia, and give pathology and treatment.

I overlooked your circular till this late date, but it will be better late than never. Yours truly,

CHARLES H. RICE, M. D.

The report of the committee was accepted, and the committee was discharged.

DR. H. F. BORDEN, of Plymouth District, said that the report showed conclusively that there exists a deplorable lack of uniformity in examinations by Censors, and that there is absolutely no rule at present by which the character or quality of the examinations in the various districts of the State may be established or regulated. In Suffolk the method adopted consists of a separate oral and written examination, and the candidate is qualified in accordance with the results of these examinations on a scale of 100. In Norfolk District, not five miles away, on the contrary, the examination is *entirely oral*. There is urgent need of some action by which there may be some degree of uniformity in the administration of this important and responsible office. Dr. Borden suggested that a certain definite number of written questions be recommended, and that candidates be subjected to the same number of written questions in all parts of the State.

DR. ERNST, of Norfolk District, proposed that a skeleton or scheme of examination be arranged and sent to each District Board of Censors at stated intervals, which should be the uniform standard for the written examination of all candidates in the State until the issue of a succeeding outline or scheme; and that, in addition to this, the Censors of each district should satisfy themselves by an oral examination of such character as they might think best, as to the further acquirements of the candidate, and that both the oral and the written examination should be considered in the final action of the Censors. In this way the Censors of each district would feel that the examination was not more rigorous in one part of the State than in another, and would also better understand the working of neighboring societies than is possible under the present system, which is an entire lack of any system.

DR. HARTWELL, of Worcester North, presented a motion recommending an amendment to Section I. of the existing By-laws, so that lines 20–21 shall read "*and by a further examination* ('a part of' omitted) *which shall be in writing, that he has an*," etc.

DR. HOWE, of Bristol North, considers the oral examination a very important adjunct to the written examination, and thinks it should always be associated with it. Candidates usually present diplomas from recognized medical colleges, and can no doubt easily satisfy an ordinary written examination; but the By-law requires the Censors to convince themselves of the moral character of the candidate, of his age, term of study, and system of intended practice. It would not be easy to gain all this information in a wrtitten examination, and practically it could not be done.

DR. BORDEN suggested that the names of candidates for admission to the Society be presented to the Board of Censors at one meeting, and that the candidates be presented for examination at the next following meeting of the Board. By this method the Censors could easily satisfy themselves of the character of a candidate, which is a specific part of their duty, and the candidate would be presented for a further examination in writing at the next meeting of the Censors.

DR. HOWE remarked that another matter also deserved attention at the hands of the Censors. It is this: A man may go from one part of the State to another, and may be admitted to the District Society within which he then shall reside without examination. What action ought the Censors to take concerning a man long in honorable practice, who, coming from another State, shall make his residence within one of the districts of this Commonwealth?

On motion of DR. ERNST it was voted that a committee of three be appointed to take this matter into consideration, and to recommend to the Board of Councilors of the State Society some action which should secure a uniform method, and, as far as practicable, a uniform standard of examination by the several Boards of Censors in the State, thereby avoiding a misinterpretation or maladministration of the By-law in relation to the admission of candidates for membership to the Society.

Drs. Albert N. Blodgett, of Suffolk, G. W. Clement, of Norfolk, and H. F. Borden, of Plymouth, were chosen as a committee for this purpose, and instructed to report at the next annual meeting.

There being no further business, the meeting then adjourned, to meet on the date of the annual meeting of the State Society in 1885.

MEETING OF THE MAINE MEDICAL ASSOCIATION, JUNE 10, 11, AND 12, 1884.

CHARACTER OF THE MEETING.

THE meeting of the Maine Medical Association, which was held in Portland on the 10th, 11th, and 12th of June, was characterized by a large attendance, scientific activity, and notable harmony. Rarely, if ever, have more or better papers been read, livelier discussions held, or kinder feeling displayed; and with these elements the occasion could not fail to be successful and leave a pleasant memory for every one who was fortunate enough to be present.

In the reports, essays, and discussions, practice, pathology, surgery, and obstetrics, all received due attention, and there was a gratifying absence of the overload of papers on narrow specialties, against which a wailing protest has gone up all over the country in the past two or three years. We would not be understood as lacking in appreciation of the work of specialists; but it is not altogether edifying to an assemblage of general practitioners to have half their time consumed by the reading of articles written in language which they do not comprehend, and about diseases which they never presume to treat. The sentiment and temper of the profession are easily ascertained if one will notice the expression of patient en-

durance on the faces of the audience during the presentation of one of these topics which is aimed way over their heads, and the sudden change to animated interest when somebody gives his views on a disease which every physician has to see many cases of every year. They care little and understand nothing about the first subject; but on the second they find their opportunity; all can and many do take part in the ensuing talk; the impact of one view against another evokes sparks even from dull-looking material, and a general impression of profit from the debate is the result. Thus it was in this meeting of the Maine Society; some peculiar cases were described and shown, some frequently observed conditions rehearsed, and some scientific problems discussed; but through all the general practitioner felt that he was having a fair chance, and that the object which should mainly be kept in view in such assemblages was observed. Space does not permit a full account of all the proceedings, but an idea of their scope may be obtained from a brief recital.

CASES OF COMPLICATED LABOR.

DR. S. P. WARREN, of Portland, reported two cases, one of acute pulmonary œdema in labor with death from heart-clot; the other of labor complicated by a number of uterine fibro-myomata — subserous, submucous, and intramural.

ALBUMINURIA AND ACUTE RETINITIS IN PREGNANCY.

DR. SARAH ELLEN PALMER, of Portland, reported a case of pregnancy in which the patient suddenly became blind at the seventh month. Albumen was found in great quantity in the urine, and examination of the eyes disclosed severe and rapidly progressing retinitis. Labor was induced, and the patient recovered with very fair vision.

DR. JAMES A. SPALDING, of Portland, saw the case often in consultation, and gave an account of his observations. He was able to find but little literature bearing on this precise condition. Cases of albuminuria and partial blindness in gestation are common enough; but in the reported cases the condition of the interior of the eyes is not mentioned. Both the accoucheur and the oculist strongly insisted upon the necessity of an ophthalmoscopic examination in all cases of pregnancy.

DR. ALFRED MITCHELL, of Brunswick, read an interesting and instructive paper on the Treatment of the Perineum in Labor.

PHOSPHORUS NECROSIS OF JAW-BONE.

DR. S. H. WEEKS, of Portland, reported a case of monocular diplopia, one of Tait's operation, and one of phosphorus necrosis of the lower jaw-bone. In the last case half the inferior maxillary was removed, and the patient was shown with but slight deformity and a fair prospect of being able to wear artificial teeth in the place of those which are lost.

MULTIPLE FRACTURE.

DR. J. A. DONOVAN, of Lewiston, exhibited a little lad whom he had treated for fracture of the parietal, comminuted fracture of one femur, compound fracture of the other, from which it was necessary to remove a large piece of the lower portion of the diaphysis. The boy walks with a decided limp, but gets around easily and well. Dr. Donovan also reported a case of tumor of the kidney, and a case of death from meningeal inflammation of the brain, originating in chronic non-suppurative inflammation of the tympanum.

DR. H. E. HILL, of Saco, gave the history of six ovariotomies, with five recoveries, though most of the cases were complicated.

DR. S. LAUGHTON, of Bangor, read a paper on the Relation of Micro-organisms to Disease.

DR. I T. DANA, of Portland, introduced the subject of obscure cases of typhoid fever in some extemporaneous remarks.

DR. C. W. BRAY, of Portland, reported a case of apoplexy in a girl of fifteen years, with the post-mortem appearances.

ETHERIZATION.

DR. F. H. GERRISH, of Portland, presented a method of recording cases, which so greatly simplifies the process as to tempt one to try it, and he likewise gave the result of some quite extensive observations on etherization, directed mainly to the prevention of vomiting. Full doses of bromide of sodium for twenty-four hours before the anæsthetization seemed to protect measurably against stomach disturbance, though this medication apparently prolonged the time of administration of the ether.

THE PRESIDENT'S INAUGURAL ADDRESS.

The President, DR. OREN A. HORR, of Lewiston, in his inaugural address, reviewed the first decade of the Society's life, and made numerous valuable suggestions concerning the duties which the Association owed to the community and the profession. The one which excited most attention was that relating to the Medical School of Maine, and a committee of three was appointed to confer with the trustees and overseers of Bowdoin College, of which the School is the Medical Department, and devise means for the removal of the institution from Brunswick to Portland at the earliest possible date. For many years it has been the conviction of the profession that the School ought to be in the medical centre of the State; and now that the Maine General Hospital is to be enlarged and the ground is already broken for the erection of a fine operating amphitheatre, all that seems to stand in the way of the change of location that is desired is the lack of a suitable building for the School. The Alumni Association has already awakened an interest in the subject, and may doubtless be depended on to favor the project in a very substantial manner; and it is not improbable that, within five years, the institution will be in a new home, in close relation to hospitals which can furnish opportunities that have hitherto been wanting. At Brunswick there is a perfect glut of clinical material, but there is no hospital, and the School can never do its best work without hospital advantages.

THE ANNUAL ORATION.

DR. A. L. HERSEY, of Oxford, delivered the annual oration. He touched upon a number of topics, one of the most impressive of which was the matter of medical education. Usually orators and writers are eager to denounce the schools for not advancing the standard; but Dr. Hersey, unlike most other speakers excepting professors, laid the blame upon the individual members of the profession. He said that as long as physicians permitted poorly qualified men to enter their offices as students, and complain of the schools

for not granting diplomas to these stupid fellows, so long will the standard be low. But if physicians would refuse to encourage all who have not a thoroughly good preliminary education, then the schools could and would take advance ground, and the profession would make immediate and steady progress. If every preceptor would take a high stand like this, what a change would appear in most of the medical schools all over the land!

SHALL THE AMERICAN MEDICAL ASSOCIATION BE INVITED TO PORTLAND?

On the last day of the meeting a subject was broached which excited extraordinary interest. A delegate to the National Society, in his report of the proceedings last month in Washington, said that a number of the members had voluntarily expressed a lively desire to have the American Medical Association meet in Portland. As the Maine delegates had no authority to extend an invitation, New Orleans was selected as the next place of meeting; but they brought the matter to the attention of the Maine Association, with a suggestion that, at the Louisiana Convention, this State Society should offer its hospitality to the national organization. Probably the thought was new to most of our members. With characteristic Down East modesty, the profession in Portland had not presumed to think that it could offer attractions to the greatest medical body in the New World. But, being introduced, the proposition received a cordial welcome; and, as it was too late in the meeting to discuss properly so important a theme, a committee was appointed to confer with the President and Chairman of the Board of Censors relative to the whole affair, with power to add to its number, and to act for the Association in any way which seemed expedient. Perhaps the scheme may be found impracticable, perhaps it may be easily feasible. At all events, it will be thoroughly examined, and the medical public shall be seasonably informed of the conclusion. The committee consists of Drs. Weeks and Gerrish, of Portland, Laughton, of Bangor, A. J Fuller, of Bath, and A. Garcelon, of Lewiston.

NECROLOGY.

Four members, all well advanced in years, have died during the year: Drs. John T. Gilman and J. S. Goodwin, of Portland, Wm. Swasey, of Limerick, and C. W. Whitmore, of Gardiner.

Between twenty and thirty candidates were admitted at this meeting.

OFFICERS ELECT.

The officers for the coming year are as follows: President, Thomas A. Foster, of Portland; First Vice-President, Sumner Laughton, of Bangor; Second Vice-President, Abial Libby, of Richmond; Corresponding Secretary, S. W. Johnson, of Belfast; Recording Secretary, Charles D. Smith, of Portland; Treasurer, Augustus S. Thayer, of Portland; Board of Censors, George H. Cummings, of Portland, B. F. Sturgis, of Auburn, E. Adams, of Litchfield, H. E. Hill, of Saco, A. L. Hersey, of Oxford; Publication Committee, the Recording Secretary *ex officio*, Charles O. Hunt, of Portland, C. A. Packard, of Bath, C. G. Adams, of Portland, J. O. Webster, of Augusta; Business Committee, Irving E. Kimball and C. D. Smith, of Portland; Orator, Stephen H. Weeks, of Portland.

The next meeting will be held in Portland on the econd Tuesday in June, 1885.

CHICAGO MEDICAL SOCIETY.

REGULAR MEETING, JUNE 16, 1884.

THE first paper was ably presented by DR. WM. E. QUINE, of which the following synopsis is appended: —

SIGNIFICANCE OF JAUNDICE IN DIAGNOSIS.

After alluding to jaundice of obstructive and non-obstructive origin, and to the various theories that have been advanced in explanation of the latter, the writer succinctly pointed out that the attendant symptoms were mostly due to the presence of colorless bile acids, — the bile pigment being harmless. Cerebral disturbance due to hepatic derangement and associated with cholæmia was not caused by the presence of normal bile, but by a different though unexplained species of toxæmia.

Although slight jaundice is often overlooked, and in some instances cannot be distinguished from cachexiæ except by the discovery of bile acids in the urine, the diagnosis usually relates to the discovery of the cause and not to the mere recognition of the effect The following seventeen points complete a summary of the paper: —

(1.) Jaundice occurring suddenly, in apparent health, and painlessly, is usually of emotional origin, and transitory.

(2.) When it depends on disease or injury of the brain, acute atrophy of the liver, snake poison, or an infectious fever, it is always associated with mental disturbance.

(3.) If it be attended with fever, and well marked, it is secondary to inflammation of biliary passages, pneumonia, toxæmia, or infective inflammation of the portal vein.

(4.) If it occur suddenly, and is preceded by paroxysmal pain and vomiting, it is caused, nine times out of ten, by biliary calculi.

(5.) If it is preceded by typical symptoms of gastro-duodenitis it is obviously of catarrhal origin.

(6.) Impassable obstruction of the common duct is shown by great intensity of jaundice, clay-colored stools, and in recent cases by distention of the gall-bladder.

(7.) Jaundice caused by sudden obstruction of the biliary passages is always associated with paroxysmal pain and nausea; but there is no means of ascertaining the nature of the obstructing body except its discovery in the stools.

(8.) In the rare cases of sudden obstructions by cancerous, hydatid, and aneurismal tumors, there is almost always a history of impaired health, enlargement and deformity of the liver, ascites, etc., which, aided by the revelations of physical exploration, will lead to correct differentiation.

(9.) Sudden return of normal coloring to fæces confirms the diagnosis of obstruction.

(10.) Occlusion of the cystic duct may be attended with as much pain, nausea, and distention of the gall-bladder as occlusion of the common duct; but there is no jaundice. In occlusion of the hepatic duct the same symptoms are present, including jaundice, and excluding distention of the gall-bladder. It is often impossible to distinguish between occlusion of the hepatic, and the common duct. The former is rare because the duct increases in size from above downward.

(11.) If jaundice persist after the symptoms of biliary colic or catarrhal inflammation have, a month since, disappeared; or if jaundice have disappeared after a

biliary colic, to return slowly and painlessly, it may be assumed that stricture of the duct has resulted from inflammatory thickening, adhesion of walls, or cicatrization of an ulcer.

(12.) A history of repeated attacks points to the probability of gall-stones.

(13.) If jaundice come on slowly, without antecedent colic or catarrh, and without attendant evidence of impaired health or portal obstruction, it is probably caused either by pressure upon the duct, or by the growth of a tumor within its walls. The pressing body, when large enough, may be readily appreciated, as in the case of pregnancy, ovarian tumor, aneurism, distended colon, etc.; but when it is small, or constituted by enlargement of lymphatics in the fissure of the liver, it is apt to escape detection.

(14.) Slight but persistent jaundice may be due to incomplete occlusion of the common duct, or to complete occlusion of a branch of the hepatic, but usually it is found associated with either valvular disease of the heart, some disease of the lungs which obstructs circulation, or cirrhosis of the liver.

(15.) If ascites be associated with it the disease is either cirrhosis or cancer of the liver. If the liver be abnormally small the disease is cirrhosis; if it be large the disease is either hypertrophic cirrhosis or cancer. Differentiation between the two is seldom attended with difficulty.

(16.) Absence of jaundice does not imply absence of hepatic disease, since the liver may be destroyed by disease or extirpated by operation without jaundice ensuing.

(17.) It is not a prominent symptom of hepatitis if catarrhal inflammation of biliary passages be rigidly excluded. It is not characteristic of hepatic abscess where, at most, mere muddiness of the complexion is usually seen. These affections are rare in temperate latitudes, and when encountered are generally found to be secondary to direct injury of the liver, or to infective inflammation of the portal vein. It is not a symptom of waxy or fatty liver or of hydatids excepting as an extraordinary complication.

DISCUSSION.

DR. G. C. PAOLI. There is no doubt but what in serious maladies of the liver there may be present only slight symptoms of jaundice sometimes. In scirrhus of this organ the tint of pigment in the conjunctiva and elsewhere may amount to but little; there may be no "bilious" excretions in the bowels, and icterus may be almost unperceived, and the diagnosis early made is apt to be overlooked.

DR. S. H. STEVENSON inquired more particularly of the writer if he stated that cholesterine is toxic, or that obstruction of the gall-duct, or either of these conditions, produces cerebral disturbances.

DR. J. J. M. ANGEAR. If clay-colored stools and the odor comes from the large intestine, and the small intestine has nothing to do to produce these conditions, or the bile either, then he could not understand why the liver excreted bile. To give mercury produces dark-colored offensive stools, because why? because it affects the large intestine or the liver. Physiology says bile destroys the red corpuscles of the blood. If the coloring matter of the bile is nothing more than the coloring matter of the blood, then why not take the position that some poison enters the blood, and that the color of the conjunctiva and mucous membrane has nothing to do with the liver.

DR. A. R. JACKSON expressed his admiration of the paper, that it should be emulated, as it was not "sophomore" in style, and that it was full of good points, and devoid of superfluous verbiage.

DR. J. H. ETHERIDGE inquired of the author if in mental emotion people did not at times become greatly jaundiced? Also, is it not a fact that pigmentary substances contain more than one kind of coloring matter? In those who are injured where icterus appears, is it due to reaction to the vascular or nervous condition? or merely to shock?

DR. C. T. FENN thought that in people who died from hepatitis the surface might become jaundiced in appearance.

DR. QUINE closed, but did not pretend to attempt answering all the questions, nor could he refer the speakers to any authority whereby they could be answered. He stated, however, that it has not been proven that bile is toxic, or that it produces cerebral disturbances, for the blood and secretions may be saturated for years with it and no cerebral disturbance ensue, and in obstruction of the common duct no symptoms of cerebral disturbance may be developed. Regarding the prevalence of jaundice in scirrhus of the liver this is erroneous. He did not know that jaundice occurred after death.

The second paper, by DR. G. F. HAWLEY,

THE EFFECT OF NOISES UPON CERTAIN FORMS OF DEAFNESS,

was attentively heard. A synopsis follows: —

More than two hundred years ago Dr. Thomas Willis, of Amsterdam, described a certain form of deafness in which hearing was improved by noise, which enabled persons to distinguish tones and sentences which at other times would be unheard. This symptom, bearing the name paracussis Willisiana, has been accepted by most aurists, but no satisfactory explanation as to its cause has been advanced.

While Politzer, Von Troltsch, and others consider that it depends upon some change in the position of the ossicles or membrana tympani, many like Kramer take different views, and believe that it is due to a stimulating of the auditory nerve, thus forcing it to a more healthy action. Experience favors the theory that the middle ear is the seat of this symptom; that some change is brought about by the constant noise which restores the hearing for the time being. What this change is, is still open to discussion. It may be of interest to relate the following case, which came under the care of the reader while house surgeon at the Golden Square Hospital, London. Mrs. H., aged thirty, had for the last five years suffered with marked deafness in both ears. Common conversation was heard with difficulty, except when any loud noise was present. At that time the hearing was apparently greatly improved. A watch could be heard on the left side only upon contact, and on the right at a distance of about two inches. The tuning-fork showed no trouble of the acoustic nerve, but clearly indicated some disturbance of the middle ear. The drum-head was normal as to tension, color, etc., while perfect movability existed in the malleo-incuidal joint. Nothing indicated anchylosis of any of the ossicles. The appearance of the throat was healthy, and the Eustachian tubes both patent. This is a good example of this form of deafness, in which

the symptom of hearing better in a noise manifests itself. Roosa, however, mentions two cases where the drum-head was more or less destroyed, and still noises improved the hearing. The ossicles in both cases were intact.

Politzer in his work on Aural Surgery states that this improvement is seen only in middle-ear affections of an adhesive or sclerotic character, and regards it as a most unfavorable symptom for satisfactory prognosis. Roosa, on the contrary, states that it is found in many forms of ear affections, and does not necessarily forbid one from expecting favorable results from treatment. In his article on The Effects of Noises upon Diseased and Healthy Ears, he says: "I have known two cases where this symptom occurred in patients who regained their hearing perfectly." While the symptom frequently accompanies incurable diseases of the middle ear, the writer believes it is a very frequent symptom in sub-acute cases where both ears are affected. Of course it would not be observed in disease of one ear only. Whatever may be the cause of this symptom, we are justified, the writer thinks, in believing that certain pathological changes are then present in the middle ear which will be found at no other time. If this be true, in what does the change exist? Willis considered the change brought about by the action of strong wave tones upon a relaxed membrana tympani to be the cause of this symptom. As long as the drum-head is in a relaxed condition it refuses to respond fully to wave impression. It is no longer a perfect sound conductor until its tension is restored. Noises, by forcing air against the membrane, press it inward, restore its tension, and hearing is improved until the pressure is removed when deafness returns as bad as ever. If this improvement was found only in such cases as he describes we might accept his theory as correct, but unfortunately, as already stated by the writer, it is present with no change whatsoever in the drum-head. Therefore in such cases at least this improvement in hearing is due to some other cause. We have in the middle ear two other elastic membranes, one of which takes as important a part in conveying wave impressions as the membrana tympani, any change by disease or injury would be fully as disastrous to normal hearing, that is, by this the writer means the membrane of the foramen ovale. When we consider the extraordinary fine shades of vibrations transmitted by this membrane to the fluids of the labyrinth, are we not justified in expecting that any loss of accuracy and precision on the part of the transmitting apparatus at this point will cause a corresponding loss of hearing power?

According to Riemann, the excursions of the stapes in the fainter tones are so small as to escape detection, even with the highest power of the microscope. Therefore a corresponding sensitiveness on the part of the membrane must necessarily be present in order to appreciate and transmit these vibrations. Thus we see that any change in the membrana ovalis, which tends to hinder the passage of the vibrations to the fluids in the inner ear, must cause diminution in hearing. If, then, the membrane from any cause becomes relaxed and loses the power of responding to vibrations, it acts no longer as a sound conductor, but as a damper to any wave impressions. This is demonstrated in the case of relaxed drum-heads where inflation improves the hearing. Not only must this elastic plate (so called by Politzer) be capable of responding fully to any wave impulse, but it must also bear a certain relation to the foot of the stapes, that is, a due amount of pressure must be applied by the stirrup and a sufficient resistance be offered in every ear that possesses perfect hearing. If this is lost deafness is the result. Chronic suppurative inflammation of the middle ear with destruction of drum-head, incus, and malleus is a proof of the correctness of this statement. Hearing is here frequently improved by a false drum-head, which presses the loose stapes against the membrane of the foramen ovale, thereby restoring the relative positions of the parts. In a relaxed membrane the pressure of the stapes is wanting, due to an absence of resistance in the diseased membrane itself. Until we find some means of restoring this needed resistance, deafness remains. Thus through the loss of elasticity in this membrane we lose two important factors for perfect hearing: First, this membrane like the membrana tympani while relaxed refuses to act as a conductor of sound by not responding to vibrations given it; and, second, the proper relation between it and the stapes is destroyed the necessary pressure and resistance being absent.

We find in the case of an atrophied drum-head that hearing is frequently improved by inflating the middle ear, which restores the tension to this membrane by forcing it outwards. One might suppose that such inflation would likewise restore lost hearing if due to a relaxed membrane at the oval window. Unfortunately the same act which might restore to this membrane its proper tension forces it inwards as well, and thus separates the stapes from it. Though the membrane may be in a proper condition for receiving and transmitting wave sounds, the stapes, from the absence of any pressure applied by it to this membrane, will be unable to perform its duty; there will be more or less obstruction to the passage of sound at this point. Whatever, then, restores the hearing in these cases must not only renew the tension of the membrane, but maintain as well the relative position of health between it and the stapes. This, in the writer's opinion, can only be accomplished by some influence brought to bear upon the membrane and stapes from outside the middle ear. If, now, we consider the effect of wave impulses upon the membranes and ossicles we can probably understand how a loud and continuous noise (as the writer thought) might improve the hearing where the deafness is due to such pathological changes as herein described. The air set in motion by this noise strikes upon and pushes the drum-head and ossicles inwards. This crowds the air in the middle ear against the membrana ovale, which, if relaxed, is made tense by this pressure. At the same time the relative position between it and the stapes, as to pressure, etc., is also restored, and hearing, for the time, is therefore improved. This noise, which would confuse one with normal hearing, is absorbed, so to speak, in removing the cause of deafness. In case of perforated drum-head the vibrating air acts directly upon the diseased membrane and stapes.

Von Troltsch mentions a case where a magistrate so afflicted improved his hearing by pressing a bit of stick against the drum-head. Allen also, in his work on Aural Surgery, states, while speaking of this symptom, that the hearing power was increased in a patient who presented herself with marked destruction of the drum-head by pressing cotton against the ossicles. Another is also noted where a large perforation existed. Here, before and after the healing of the perforation, hearing was improved by pressure.

Though these three cases do not in themselves place this theory beyond dispute, they may make it worthy of consideration. It may encourage us to further investigations, which, perchance, may result in establishing beyond a doubt the cause of improved hearing in certain forms of deafness by noise.

The paper was discussed by DR. S. J. JONES, who stated: This subject interests pathologists considerably; different causes will produce the condition described, and it is therefore not always dependent upon the same cause. A noise that will thus affect an abnormal ear may have none whatever on the normal ear, and cotton pressed over the stapes may also increase the hearing power of an abnormal ear. A tuning-fork placed between the teeth is also better heard in these particular cases of affected ear. The same also regarding the transmission of delicate sounds, — when the hand of a patient is placed upon a piano it will excite to action hearing in an abnormal ear of this kind.

MEDIAN LITHOTOMY FOR CYSTITIS AND HYPERÆSTHETIC URETHRA.

The following is a condensation of DR. W. L. AXFORD'S verbal report of a case, pertaining to genito-urinary surgery, occurring in a man aged sixty-six, of inherited gouty diathesis. Occupation, gardener. For the past eighteen months patient has been a great sufferer from attacks of nephralgia, which were relieved by one fourth of a grain of morphia subcutaneously for a long time. In time, however, the action of the drug, even in much larger doses, failed to relieve him; suppositories of belladonna and all anodynes also failed. Recently he had another attack continuing three days. He voided his urine frequently, perhaps every five minutes. The bladder remained full continuously, and he had also severe chronic cystitis. Catheterization produced intense agony. This was of such an excruciating character, owing to unusual hyperæsthæsia of the urethra, that, as a last resort, the median operation of lithotomy was performed to relieve him, which purpose it accomplished admirably. A drainage tube inserted was repeatedly obstructed with mucous and phosphatic deposits. The urine was very ammoniacal and fœtid, he also had enlarged prostate. He died in a few days, and autopsy revealed cirrhotic gouty kidneys and liver. He would perform this operation again in a similar case.

DR. C. T. PARKES discussed the above case, and stated his belief that the operation was justified; he had performed it to relieve cases of cystitis himself, and briefly cited two instances when he had relieved each of them for six months.

The last speaker then presented a verbal report of a case of

PAPILLOMATOUS MULTILOCULAR CYSTS OF BOTH OVARIES,

and exhibited the specimen, his remarks, of which we append the principal points, are as follows: —

The specimen consisted of papillomatous multilocular cysts of both ovaries. The cysts had ruptured and discharged their contents into the peritoneal sac. The history of enlargement embraced a period of only six months. The patient stated she never had an illness previous to the commencement of the abdominal enlargement. She emaciated rapidly and to great extent; patient measured forty-four inches in circumference at height of umbilicus. The greatest difficulty in the case was the differentiation between ascites and ovarian cyst. There was no œdema, nor had there ever been, of the lower extremities. Percussion gave dullness in all directions, lying, standing, or sitting, the only point of resonance being in the epigastrium; here fluctuation was very distinct in all directions on the slightest touch. Pelvic examination revealed that fluctuation was not to be felt in the pelvis. Also determined the presence of a small growth about the size of the closed fist on right side. The uterus was displaced forwards close to the pubes; cul-de-sac of Douglas filled with foreign body. Diagnosis: Ovarian tumor, ruptured sac, and contents emptying into peritoneal sac.

Operation. Forty-four pints of fluid were evacuated from the abdomen and tumors; fluid of dark amber color. No large amount of lymph precipitated in it after standing. Both ovaries were found diseased, there being present on the right side a ruptured papillomatous tumor, which still contained some fluid that could be pressed out at the site of the papillary growth. The right one had not ruptured, but was bound down deeply in the pelvis by adhesions. The true pelvis was filled by the tumors and their adhesions. With great difficulty the tumors were enucleated and removed. During the first four days after the operation her temperature had not reached 100° F., the patient being strong and cheerful. Bleeding was quite free immediately after the separation of the adhesions, but soon ceased altogether under pressure with dry sponges. A drainage tube was left in the lower end of the incision down to the bottom of the pelvis, anticipating free discharge from such an extensive raw surface, which was very free through it for two days. Six days after the operation the temperature is normal, and whilst there is danger yet there is not much doubt of her ultimate recovery.

Discussed by Drs. A. R. Jackson, C. T. Fenn, and R. Tilley.

At a late hour the Society adjourned. L. H. M.

Recent Literature.

Clinical Chemistry. An Account of the Analysis of Blood, Urine, Morbid Products, etc. By CHARLES HENRY RALFE, M. A., M. D., Fellow of the Royal College of Physicians, London, etc. Illustrated with Sixteen Engravings. Philadelphia: Henry C. Lea's Son & Co.

This work, the author tells us, has been written to furnish students and practitioners with a concise account of the best methods of examining chemically abnormal blood, urine, morbid products, etc., at the bedside or in the hospital laboratory. In the first two chapters the nature of the processes going on in the body under normal conditions and the properties of the chief organic and inorganic constituents of the body are briefly considered. Then follow chapters on Blood, Morbid Conditions of Urine, Morbid Conditions of the Digestive Secretions, and Morbid Products.

We are surprised to find so many misspelled words and incorrect formulæ in a book of this kind. The most noticeable examples of the former are "Pettenkoffer," Draggendorf," "Woolaston," "ptoamines." Some words are repeatedly misspelled. Most of the incorrect formulæ are undoubtedly errors of the printer; some are, apparently, not; as, for instance, the formulæ

for the normal and acid sodium carbonates, which are repeatedly given incorrectly. The author apparently wrote his book hastily, and revised the text, if at all, very carelessly.

We find some statements in the book with which we do not agree. For example, we do not consider the volumetric estimation of chlorine, by means of mercuric nitrate, simpler and more reliable than the estimation by means of silver nitrate. His directions for the preliminary examination of the tissues for morphia and strychnia in cases of suspected poisoning cannot be recommended. Some of the illustrations are very inferior.

This book can, we think, be made a very useful one. It needs, however, very careful revision. The chapters on Blood and Urine, which are really the most important practically, and which occupy, as is proper, a relatively large portion of the book, should be made more complete. The value of the book would thereby be increased.

Medical and Surgical Journal.

THURSDAY, JULY 3, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE WESTWARD COURSE OF CHOLERA.

THERE is no longer any possibility of concealing the character of the disease which has manifested itself at several different points in France, and it is evident that true Asiatic cholera has found a foot-hold on the western shores of the Mediterranean at places with which the rest of Europe and this continent are in active commercial communication. Though such a sequence to the epidemic which ravaged Egypt last year was long ago anticipated, its actual occurrence is none the less startling; and whilst there is no occasion for panic or ill considered and exaggerated action, especially in this country, a careless sense of security would be quite as ill timed.

The disease seems to have been brought to Toulon by a government vessel, the Sarthe, whose commander is reported to have committed suicide from mental distress at his relation to such a disaster, and the first case occurred there, apparently, about a month since. The government resorted to a policy of concealment at first of the fact that there was sickness at the naval yards, and subsequently of its nature, and even now that cases are reported at Marseilles and at Paris there is more than a suspicion that its full extent is not made public. Such a policy, whether in regard to cholera or yellow fever, is a mistaken and usually disastrous one, and should find as little favor with civilized commercial people as the old-fashioned quarantine or attempts to control the course of such plagues by burning fires in the streets and sprinkling them with disinfectants.

As we write the latest advices announce eight or ten deaths daily in Toulon in the navy yards and in the town, with sixty-two patients in the naval hospitals.

No clean bills of health are issued to vessels leaving Marseilles; Gibraltar refuses entrance to French ships; overland passengers from France are subjected to five days quarantine at Rome; and Spanish authorities threaten a quarantine of from ten to fifteen days against all English shipping unless England adopts what they would consider satisfactory precautions against the introduction of the disease, which it is not probable England will do.

All this illustrates at once a general conviction of the seriousness of the situation, and the little progress made since the International Congress of Vienna, in 1874, by the different European countries toward a rational and uniform policy of controlling the spread of epidemics. The general principles announced by that Congress formed a decided advance upon the irrational mediæval practices to which some of the participating countries still clung and still cling, but it was clearly recognized by the majority of the delegates that any genuine progress toward uniform practice must be based upon a prolonged conjoint investigation of the laws governing these epidemics and of the various conditions to be met. Such an investigation it has been impossible hitherto to secure. We all remember the little favor shown the attempt by our own government, in 1881, to promote, through a congress at Washington, an international system of notification of disease.

It is probable that these questions will come up at the approaching Medical Congress at Copenhagen, or at the Health Congress at the Hague in August, and it is to be hoped that some practical results may be reached. A German commission, of which Professor Pettenkofer and Dr. Robert Koch are members, have now under consideration the proper measures to be adopted in that country against cholera, and their report is expected with impatience.

Unquestionably the first, the most important, and the most feasible precaution in any country or in any particular city is to require cleanliness in public and in private places, to guard against an infection of water supplies, to encourage individuals to live wholesomely. A thorough system of inspection should be organized, and at sea-port towns suspicious vessels must be fumigated, those actually sick secluded, and other passengers — should circumstances or public feeling demand it — may be subjected to a limited quarantine of from five to seven days. The period of incubation of cholera, however, — as of other infectious diseases, — is a variable one, and England is right in declaring it to be easier and more profitable under the exigencies of modern commerce to remove the soil than to exclude the seed.

Between the end of May and the end of September there is ample time for cholera to cross the Atlantic. Common prudence demands that the authorities in all

our large cities, and particularly those on our Atlantic sea-board, should be strenuous in their exertions to abolish all nuisances and sources of filth. Such labor is sure to be rewarded in the diminution of sickness from other causes than cholera, and will in no event be lost.

STRETCHING THE INTERCOSTAL NERVES.

THE intercostal nerves have again been stretched for neuralgia, and successfully, at least so far as the operation and its immediate effects were concerned, as we learn from Dr. L. v. Lesser.[1] The patient was a woman of sixty-one, and the neuralgia, of seven years' standing, occupied both sides of the chest from the fourth to the tenth rib, and both breasts. In spite of the fact that both mammillary glands were greatly atrophied, a few drops of milky fluid could be pressed out of them, and it is especially noteworthy that this secretion increased during the exacerbations of pain, which recurred with great violence every night. The operation was decided on as a purely symptomatic measure, notwithstanding the fact that the neuralgia was believed to be due to pressure — possibly of distended rachidian veins — upon the nerve-roots. Seven intercostal nerves were laid bare and forcibly stretched, one after another, all of them upon the right side.

The wound (a single long cut through the skin) healed by first intention, and without material accident, considering the age of the patient. The patient left the hospital without having had any return of the neuralgia beyond a few slight pains, and remained equally free for two months, when she died.

The writer makes some important suggestions with regard to the details of the operation. The nerve, he says, should be sought for not just beneath the rib, as is usually stated, but *behind* and beneath it, in a triangular space bounded by the rib, the intercostal fascia, lying between the two sets of intercostal muscles, and the internal layer of muscle, which is attached some distance up on the posterior surface of the rib.

Failure to remember this fact that the nerve (and vessels) is to be sought for rather behind the rib than on a level with it would lead the operator, he thinks, into the danger of penetrating the pleura, which was in this case avoided.

A COMMISSION TO CONSIDER THE RELIEF OF RIVER BASINS AND PROTECTION OF WATER SUPPLIES.

THE last Legislature of Massachusetts passed a resolve for the appointment of a commission to consider a general system of drainage for the relief of the valleys of the Mystic, Blackstone, and Charles Rivers, and certain other portions of the Commonwealth, and for the protection of the public water supplies of the cities and towns situated within the basins of these rivers, such commission to consist of five persons, of whom no two should be residents of one municipality. A previous commission, consisting of two physicians connected with the State Board of Health and one sanitary engineer, reported to the Legislature three years ago, considering especially the condition of the Blackstone River, into which the sewage of the city of Worcester was being emptied, greatly to the annoyance of towns below. No action was taken at that time, and the commission was dissolved.

No more important question in the immediate future awaits the action of the legislatures of this and other thickly-settled Eastern States, in which extensive manufactories add their refuse to the sewage of a large and growing population, thereby complicating a problem already sufficiently serious. A certain profit may be derived from studying the experience of other and older communities who have been grappling with these questions already for a number of years with varying success. The conditions, however, change so greatly in each country with soil, climate, rainfall, and dilution of sewage that results elsewhere can only be accepted as applicable anew after the most careful study and revision.

This commission is expected to consider the various methods of disposal of sewage and the application of such methods to any portion of the territory mentioned, and to report its conclusions in print to the Legislature of the year 1886, or to that of the year 1885, if practicable, for a portion or the whole of the territory, and to consider and report upon the needs of any other portion of the Commonwealth as to the disposal of sewage and the protection of the public water supplies. It must also include in its report suitable maps and plans of the territory to be drained, an estimate of the cost of the work, and a recommendation as to the methods of apportioning the cost. The commissioners are to receive such compensation for their services as the Governor and Council may determine, provided that the whole amount expended under the provisions of the resolve shall not exceed twenty thousand dollars; and their term of office shall not extend beyond January 31, 1886. Power is given to employ such engineering and other assistance as may be necessary for carrying out the objects of the resolve.

The commission as named by the Governor consists of two lawyers, one manufacturer, and two men of business. There should unquestionably have been at least one medical man, especially acquainted with the questions involved, among the number. The expert knowledge of the engineer may be easily and probably better supplied from the appropriation than by appointment upon the commission.

The report will be awaited with great interest by those who for some years past have been impressed with the urgency of the subject, and should be a valuable document, which we hope may be so conceived as to attract the support of our legislators to wise measures.

[1] Deutsch. Med. Wochr., No. 20.

— The advent of Asiatic cholera at a number of places on the Mediterranean Sea is announced.

MEDICAL NOTES.

— Dr. Fordyce Barker is reported to have said that for two years he has directed his nurses never to give a vaginal injection, unless especially ordered, in the puerperal state. Experience has taught him that patients did better than when antiseptic vaginal injections were used in a routine manner.

— Some workmen engaged in excavations in the bail within the boundaries of the old Roman city at Lincoln lately came across a crematory furnace and a sarcophagus. In the latter were found ten urns, which contained dust and calcined bones. The urns were of different sizes and shapes, and were all provided with saucer-shaped covers. Only one of them, however, was got out perfect. The interior of the sarcophagus was lined with long, thin bricks, which perished on being exposed to the air.

— Dr. Wythe, in the *Pacific Medical and Surgical Journal* for March, 1884, says: "The sanitary condition of the great cities of the world to-day is vastly better than of those of the Middle Ages, although very far from what common prudence deems desirable. It is still true that people live longer in rural districts than in cities, yet ever since civilization began to inquire into and regulate public hygiene there has been steady improvement. Statistics may not yet be fully reliable, yet the best we have prove that life has been prolonged by civilization. According to Wagner, 'In the twentieth year of life the probable survival was in the sixteenth century twenty-two years; in this century forty years.' Among children the death-rate depends upon the social position or high civilization of the parents. In England, according to the tables of Mr. Ansell, of 100,000 children born alive 74,000 will live at the end of their fifth year; but among the upper classes, who can afford the appliances of modern life, there will be 87,000, and among the peerage there will be 90,000."

— The Paris correspondent of the *Lancet* sends an account of an invalid artillery soldier at Landrecies, in the Department of the North, who was wounded in the late Franco-German War, when he was horribly mutilated by the bursting of a Prussian shell. The man's face was literally blown off, including both eyes, there being left behind some scanty remnants of the osseous and muscular systems. The skull, which is well covered with hair, was left intact, so that the man had a most hideous and ghastly appearance. This disfigurement has been completely concealed by a mask, which was made for him under the direction of the principal medical officer of Val de Grâce, in Paris, whither he had been transferred from the field ambulance. The mask was constructed by a surgeon-dentist named Delalain. It includes a false palate and a complete set of false teeth, and it is so perfect that the functions of respiration and mastication, which were necessarily imperfectly performed, are almost completely restored to their normal condition, and the voice, which was rather husky, has resumed its natural tone. The man speaks distinctly, the sense of smell, which had entirely disappeared, has returned, and he can even play the flute. He wears two false eyes, simply to fill up the cavities of the orbits, for the parts representing the eyelids in the mask are closed. In fact, the mask is so well adapted to what remains of the real face as to be considered one of the finest specimens of the prothetic art that could be devised. The man himself, whose name is Moreau, and who is in perfect health, is looked upon as a living curiosity, and travelers go a good deal out of their way to see him. His face, or rather his mask, is, of course, without any expression, but his special senses, particularly that of touch, are extremely developed, and he goes by the sobriquet of "l'homme à la tête de cire." He wears the military Cross of Honor, and delights to talk about what he went through during the war. To add to his meagre pension he sells a small pamphlet containing a full description of his wounds and of the apparatus that has been so skillfully devised as to render him at least presentable to his fellow-creatures.

— Dr. R. Guaita, in the *Gaz. degli Ospitali*, quoted in the *Bull. Gén. de Thérapeutique*, has been advocating the use of benzoate of sodium in the summer diarrhœa of children. A belief in the zymotic nature of this disease has led him to give the benzoate in doses which would ordinarily be looked upon as dangerously large for infants. He uses four to six grammes of the drug in the twenty-four hours after an initial purgative dose of calomel. Milk and soup are absolutely forbidden, and the diet (except in nursing infants, who are allowed the breast every six hours) is limited to a little wine and lemonade. In spite of these heroic measures (or shall we say because of this radical onslaught upon the microbes?) the results reported were very good. In a series of fifty-three cases, between the ages of six and twenty-four months, all recovered; thirty-five in whom the disease had lasted from twenty-four to thirty hours, in four to eight days, while the remaining eighteen, in whom it had existed from six to fourteen days, all recovered in about twenty-one days.

NEW YORK.

— The usual corps of fifty physicians for service in the tenement-house districts during the summer were appointed by the Board of Health June 24th. They go on duty on the 6th of July.

— The judgment which was rendered over a year ago by Justice Van Vorst at Supreme Court, special term, against the "United States (Eclectic) Medical College," depriving the institution of its charter, was affirmed in May, 1883. From that judgment the defendants appealed to the Court of Appeals, and the latter has just handed down a decision affirming the judgment. As the attorneys for the "Buffalo College of Physicians and Surgeons" stipulated to let the case against that school abide the event of this suit, the decision disposes of both of these bogus colleges.

— At Grace Church, at Broadway and Tenth Street, some exciting scenes occurred on the afternoon of June 24th. By the fall of a derrick used in the con-

struction of a stone spire now in course of erection to replace the old wooden one at the top of the bell-tower two workmen were seriously injured, one of them fatally. The latter was bound down to the logs forming the derrick platform by several wire cables, which cut into the flesh like knives, and it took four men twenty minutes to release him with cold chisels and hammers. In the meanwhile medical aid had been summoned, and an ambulance surgeon from St. Vincent's Hospital being the first to arrive he was just in the act of ascending to the scene of the accident by outside ladders when five or six large blocks of stone, each weighing from 150 to 300 pounds, came crashing down upon the roof, through which the most of them broke, falling into the body of the church below. The stones were dislodged by the force of the parting of the wire cables which it was necessary to cut through. By this time an ambulance surgeon from the New York Hospital had also arrived, and he succeeded in reaching the injured man, who was terribly mangled. When his wounds had been dressed, the question arose how he was to be gotten safely down, as the only means of descent was a steep and narrow ladder. Finally it was determined to invoke the aid of the fire department, and a life-saving apparatus having been procured he was by means of this carefully lowered to the ground, an immense crowd of spectators watching the descent with breathless interest. He was then placed in an ambulance and carried to the New York Hospital, where he died on the following day.

— Dr. Henry G. Piffard has again gone back to the University Medical School, having received the appointment of clinical professor of dermatology. Drs. F. R. S. Drake, Joseph E. Winters, N. M. Shaffer, and P. A. Morrow, instructors in the same college, have been promoted to be clinical professors respectively of medicine, diseases of children, orthopædic surgery, and venereal diseases.

— Dr. Macartney, Deputy Health Officer since 1867, has resigned his position and gone to Europe for a year or two's rest. He served successively under Drs. Swinburne, Carnochan, Vanderpoel, and Smith, and had full charge of the quarantine hospitals from 1869 to 1876. During 1867 and 1868, when there was an epidemic of cholera, the disease having been imported by several English steamships, he attended more than 150 patients with it from the emigrant vessels, and in 1872 he took charge of the soldiers suffering from yellow fever at Governor's Island.

— Dr. John G. Adams died on the 19th of June at Liverpool, where he had recently arrived, having sailed from New York May 14th. He was a dignified and scholarly gentleman of the old school, and for many years had been corresponding secretary of the New York Academy of Medicine. He was born in New York August 12, 1807, and having completed his academic education at Yale, pursued his medical studies at the College of Physicians and Surgeons, where he was graduated in 1830. He was the first president of the New York Medical and Surgical Society, and in 1852 began to edit the *New York Medical Times*, of which four volumes were published.

Correspondence.

RESTORATION OF GUMS ABOUT LOOSE TEETH.

THE formation of pockets between the roots of teeth and the surrounding tissues is one of the most troublesome conditions which the dentist is called upon to treat. As present methods of treatment are seldom satisfactory, some of the readers of the JOURNAL may think the following one worth trying. Only one jaw should be worked upon at a time. An impression of this should be taken a week or more before the operation, and a plate struck to cover the teeth. It is not always necessary for this to cover all the teeth. In many cases it can be fitted about the sides, leaving the crowns bare.

The teeth are then to be cleaned with sharp instruments, and the edges of the alveoli scraped in the ordinary way. All the débris is to be carefully syringed out from between the roots and the surrounding tissue, after which the following solution is to be injected into the pockets: —

℞ Thymol . . . . . 10 grammes.
Absolute alcohol . . . . . 100 grammes.
Mix.

Fine sponge which has been soaked in a germ-destroying solution and then dried is next to be cut into pieces, moistened, and carefully placed in the largest pockets, as, for example, those often seen between the molars, where, it is evident, that by the ordinary treatment we could not get a restoration of the lost tissues. The solution already given, if diluted with ten times its bulk of alcohol, answers as well as another for treating the sponge.

The metal cap, made of the proper shape to allow of new tissue growth about the denuded roots, is now placed in the mouth, and the patient sent away, after directing him to remove the plate at least six times a day, in order thoroughly to rinse his mouth with whatever simple wash may be prescribed.

Each day for the first week the pockets should be thoroughly cleaned by injecting into them by means of a fine-pointed syringe the following solution: —

℞ Nitro-sulphuric acid . . . . . 1 gramme.
Water . . . . . 100 grammes.
Mix.

During the second and third week the same treatment is to be followed by the patient, who should be seen every third day to have the injections repeated at the necessary points. After this the plate can be taken out of the mouth. This treatment is sometimes quite successful.

WILLIAM HERBERT ROLLINS.

June 19th.

Miscellany.

A CASE OF EPILEPTIC AUTOMATISM.

AN interesting case of epileptic automatism is described by a writer in the *Lancet* (May 31st).

A young man has for four years been subject to attacks of petit mal. He does not fall, but seems to "fix" his eyes, and sometimes walks forwards, or sideways, at others sits down, and generally ends by going to sleep. There are neither convulsions, nor frothing at the mouth, nor tongue biting. The only warning is that he suddenly begins to wonder whether he is going into an attack, and then he loses consciousness. He

does not think he ever dropped anything out of his hand, but he has spilt tea out of a cup. In some of the attacks he will stop what he is doing and seem to "study" for a time, but in others he will go on doing what he was engaged in at the time.

A. On one occasion, while alone in the house, he had been playing the oboe, and was just turning over some music when he lost himself, and knew nothing more for an hour and a quarter (he happened to know the time); when consciousnesss returned he was lying on the sofa still alone in the house. He, however, must have, during the state of unconsciousness, put the oboe properly away in its case and taken out the reed, for it was uninjured in its place when he came to himself. Now, this taking the reed out of an oboe is an operation requiring very delicate manipulation.

B. Another day he was with several musical friends. I think he had been accompanying some of them on the piano. He was standing at the table turning over some pieces of music when they saw him go into an attack. While it was obvious to them that he was in a fit, for they had seen him before, he took up a piece of music, went to the piano, and played it; he was quite unconscious afterwards of having done this.

C. In his father's mill there is a machine for winding warps, which is not under the special care of any one, for, when started, it works for some time by itself; but occasionally a warp breaks, and when this takes place any one who happens to see the broken end of the warp hanging down stops the machine, "piecens" — that is, joins, — the ends, and starts the machine again. Now, one day his father and others saw him go into an attack ("fix" his eyes and walk forward); and while he was in it he passed this machine, in which a broken warp was at that moment hanging down. He stopped the machine, — which is a peculiarly complex action, for it must not be stopped suddenly, but has to be let down or "slowed" by degrees — he tied the broken ends, and then started the machine again. All this he did while obviously quite unconscious, and then he passed into the usual drowsy ending of the attack.

The writer points out that these phenomena were not those of purposive epilepsy; that they did not constitute the fit, but occurred in spite of it. According to Hughlings Jackson, if the epileptic discharge be limited to parts essential to higher consciousness only, and lower areas are left untouched, these, being freed from control, will act automatically, sometimes with even hyperphysiological activity, in response to any stimuli which fall in their way. Possibly these stimuli may have been in the case *A* the remains of intentions already cerebrally formulated, or they may have been sense impressions received while in the unconscious condition in the case *C*. But the seemingly violitional character of these "automatic" acts is difficult of comprehension under any view.

Deaths reported 2643 (no reports from Buffalo, St. Louis, and Providence): under five years of age, 1149; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 629, consumption 386, diarrhœal diseases 279, lung diseases 99, diphtheria and croup 74, measles 68, scarlet fever 68, typhoid fever 40, whooping-cough 29, malarial fevers 22, cerebro-spinal meningitis 19, erysipelas nine, puerperal fever nine, small-pox eight. From *measles*, New York 30, Chicago 22, Philadelphia, Brooklyn, and New Orleans four each, Pittsburg three, Cincinnati one. From *typhoid fever*, Pittsburg nine, New York and Chicago five each, District of Columbia four, New Orleans and Nashville three each, Boston two, Brooklyn, Baltimore, Cincinnati, Milwaukee, New Haven, Lowell, Springfield, New Bedford, and Bridgewater one each. From *whooping-cough*, New York nine, Philadelphia, Brooklyn, Boston, New Orleans, and District of Columbia three each, Chicago and Cincinnati two each, Baltimore one. From *malarial fevers*, New Orleans six, New York five, Brooklyn four, Philadelphia and Charleston two each, Baltimore, Cincinnati, and Nashville one each. From *cerebro-spinal meningitis*, New York four, Chicago, District of Columbia, and Chicopee two each, Philadelphia, Boston, Cincinnati, New Orleans, Lowell, Lawrence, Springfield, Holyoke, and Woburn one each. From *erysipelas*, New York three, Philadelphia two, Brooklyn, Chicago, Boston, and Baltimore, one each. From *puerperal fever*, Chicago, Boston, and Milwaukee two each, New York, Brooklyn, and Charleston one each. From *small-pox*, New Orleans four, Pittsburg two, Philadelphia, and Cincinnati one each.

In 104 cities and towns in Massachusetts, with an estimated population of 1,393,863 (estimated population of the State 1,955,104), the total death-rate for the week was 15.00 against 14.40 and 16.31 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending June 7th, the death-rate was 19.6. Deaths reported 3286: acute diseases of the respiratory organs (London) 249, measles 163, whooping-cough 131, scarlet fever 62, small-pox (London 40, Liverpool three, Hull two, Birmingham, Sunderland, and Cardiff one each) 48, diarrhœa 42, fever 39, diphtheria 24. The death-rates ranged from 14.1 in Leicester to 28.9 in Oldham; Birkenhead 16.1; Bristol 16.5; Blackburn 17; Nottingham 17.3; London 18.9; Birmingham 19.4; Sunderland 20.3; Sheffield 21.0; Liverpool 22.8; Manchester 23.1; Leeds 25.5; Wolverhampton 28.6. In Edinburgh 23.1; Glasgow 25.1; Dublin 21.9.

The meteorological record for the week ending June 21st, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JUNE 21, 1884, TO JUNE 27, 1884.

MAGRUDER, D. L., lieutenant-colonel and surgeon. Granted leave of absence for one month. Paragraph 7, S. O. 143, A. G. O., June 20, 1884.

CLEMENTS, BENNETT A., major and surgeon. Ordered to relieve Major Jos. P. Wright, surgeon, of his duties as attending surgeon at the Leavenworth Military Prison, Fort Leavenworth, Kansas. Major Wright, on being relieved, ordered to report to the commanding general, Department of Texas, for assignment to duty. Paragraph 7, S. O. 144, A. G. O., June 21, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JUNE 28, 1884.

KNIGHT, J. S., surgeon, placed on Retired List.

WHITING, R., passed assistant surgeon, detached from U. S. S. Vermont, ordered to Marine Rendezvous, New York.

BABIN, H. J., surgeon, detached from Marine Rendezvous, New York, ordered to U. S. S. Minnesota.

WELLS, H. M., surgeon, ordered for examination preliminary to promotion.

LUMSDEN, G. P., passed assistant surgeon, detached from U. S. S. Pensacola and placed on waiting orders.

APPOINTMENTS. — The Governor of Massachusetts has nominated as Commissioners on a System of Drainage for the Charles, Mystic, and Blackstone River Valleys John Quincy Adams, of Quincy, Solomon B. Stebbins, of Boston, Edmund W. Converse, of Newton, Edward D. Hayden, of Woburn, and Leverett S. Tuckerman, of Salem.

BOOKS AND PAMPHLETS RECEIVED. — Official Report of the Relief furnished to the Ohio River Flood Sufferers. By R. P. M. Ames, A. M., M. D., Assistant Surgeon United States Marine Hospital Service.

Sixth Annual Report of the State Board of Health of the State of Rhode Island. For the Year ending December 31, 1883, and including the Report upon Births, Marriages, and Deaths in 1882.

Treasury Department. Annual Report and Statements of the Chief of the Bureau of Statistics on Commerce and Navigation of the United States. For the Fiscal Year ended June 30, 1883. Foreign Commerce. Washington. 1883.

Address by the Rt. Rev. Hugh Miller Thompson, D. D., at Detroit. With an Introduction by Rev. Daniel C. Roberts. Reprint by State Board of Health N. H. 1884.

Education the Means for Unifying the Medical Profession, etc. By R. A. Kinlock, M. D., President South Carolina Medical Association. (Reprint.) 1884.

Medical German. A Manual designed to aid Physicians in their Intercourse with German Patients, and in reading Medical Works and Publications in the German Language. By Solomon Deutsch, A. M., Ph. D. New York: J. H. Vail & Co. 1884.

Original Articles.

DIETETIC DELUSIONS; THEIR DELETERIOUS EFFECTS, AND THEIR RECTIFICATION.[1]

BY R. M. HODGES, M. D.

THE amount of food required by a healthy adult will surprise most persons, even those who are good feeders. While this varies with the work performed, the heat or cold of the weather, and the condition and quality of the food taken, it has been estimated that, in the case of a man in health and of average size, the total daily ration should weigh six pounds thirteen ounces 128 grains, of which one pound four ounces 245 grains consist of dry food substance, the remaining five and a half pounds being water.[2]

Authorities on the subject of diet say that nitrogen is the most essential of all foods, and that a certain amount, about 316 grains, should be taken daily by an adult man. If the minimum quantity of nitrogen (which, for the sake of argument may be put as low as 250 grains) be not consumed, the various functions of the body languish, and a degree of weakness is induced, with greater or less rapidity, according as the quantity falls much or little below 250 grains per diem. But let the consumption drop to an average of only 138 grains, which is the smallest amount necessary for the bare maintenance of life, and in a year or two (not at once, for every body contains a store of nitrogen) important modifications of the nutritive processes, with distinct predispositions to disease, will inevitably be established.[3]

These results of experimental investigation have a practical significance. They find expression in the fact that a failure to consume all the essential elements of full rations, whether nitrogenous or non-nitrogenous, will sooner or later, as in the disastrous Irish and Lancashire famines, give rise to a train of symptoms which have been justly denominated those of "chronic starvation."

From the small knowledge of the value of food possessed by individuals as well as the public,[4] a diminution in its adequate supply easily escapes attention; loss of appetite is looked upon with indifference, and the first steps are inadvertently taken towards a condition which is as full of meaning in the case of a single person as when a whole community are its subjects. The absence or the keenness of appetite affords no indication of the amount of food which the stomach will digest and the body assimilate or an individual be benefited by swallowing.

The body requires not only to be fed but filled; and the object of eating is as often to bring up past arrears as to supply present demands. Quality of food, with all the heat and force it may contain, will not make up for quantity, which is required for constructive and reparative purposes. The constant waste of flesh and blood can only be compensated for by an equivalent assimilation of actual materials. Yet, in spite of this self-evident proposition, a large proportion of the better educated classes of the community readily deceive themselves and mislead others in regard to the amount of food necessary for their welfare and nutrition.

From a practice, often beginning in infancy with the common maternal prejudice against giving solid food at a sufficiently early period and in adequate amount, persisted in through childhood from an erroneous idea that "meat once a day" is an ample supply of animal food, still continued during adolescence, especially in the case of girls, under the conceit that eating heartily, or "between meals," is neither wholesome nor lady-like, a habit of going without enough sustenance is finally established in adult life which is further perpetuated and confirmed by a great variety of influences. Among the more common may be mentioned personal temperament, disturbed mental conditions, languid in-door life, fatigue and exhaustion, theoretical dietetic prejudices, fastidiousness as to eatables, unwise distribution of meals, insufficient variety of food, too rigid domestic economy, and, preëminently, the revived fashion of tight-lacing. These, and a multitude of similar agencies, apart from pathological derangements, are well-recognized causes of deficient bodily nourishment, and prolific sources of disturbed health, revealing themselves in deficient weight, "weakness," anæmia, feeble circulation, neuralgia, cough and throat trouble, constipation, headache, backache, nausea, and a variety of

[1] Read before the Boston Society for Medical Improvement, June 9, 1884.

[2] Under ordinary circumstances a daily ration should contain something like the following proportions and quantities of its main ingredients: —

Water	5 lbs. 8 oz.	320 grs.
Albuminoids or flesh formers	0 lbs. 4 oz.	110 grs.
Starch, sugar, etc.	0 lbs. 11 oz.	178 grs.
Fat	0 lbs. 3 oz.	337 grs.
Common salt	0 lbs. 0 oz.	325 grs.
Phosphates, potash, salts, etc.	0 lbs. 0 oz.	170 grs.

This might be furnished by a mixed diet of the following foods: —

Bread	18 oz.	Altogether these quantities will contain about 1 lb. 5½ oz. of dry substance, though they weigh, in all 6 lbs. 14½ oz.
Butter	1 oz.	
Milk	4 oz.	
Bacon	2 oz.	
Potatoes	8 oz.	
Cabbage	6 oz.	
Cheese	3½ oz.	
Sugar	1 oz.	
Salt	¾ oz.	
Water alone and in tea, coffee, beer, etc.	66¼ oz.	

It will be seen that the weight of this allotment exceeds by one ounce — even when the solid matter contained in beverages is omitted — that of the analytic table which precedes it. This excess is mainly owing to the fact that in all articles of food actually used there are small quantities of matters (cellulose, etc.) which cannot be reckoned as having a real feeding value. A. H. Church. Food, Some Account of its Sources, Constituents, and Uses, London, 1880, page 49 *et seq.*

[3] Parkes, Practical Hygiene, page 173 *et seq.* Gr. Hewett, British Medical Journal, August 4, 1883, page 225.

[4] The manufacturers of cellulose and paper pulp propose, by an advancement of scientific cookery, to resolve nut-shells, wood shavings, and sawdust into wholesome and digestible food. They remind us that a pear, which when full grown in autumn is little better than a lump of acidulated wood, with careful storing for two or three months, becomes, by nature's unaided cookery, the most delicate and juicy pulp which can be tasted or imagined; and that cotton and linen rags have been converted into sugar artificially in the laboratory of the chemist. — *Paper Maker's Monthly Journal*, February 15, 1884, page 49.

At the existing (1884) International Health Exhibition, London, the "Vegetarian Society" are furnishing a sixpenny dinner to four or five hundred people daily. From a carefully kept account of the substances used for the bill of fare the following "food equivalents" have been reduced, showing that each diner receives, of

Albuminoids	.63 oz.
Fat	.44 oz.
Carbo-hydrates	3.17 oz.
Mineral matters	.09 oz.

Physiologists lay down the standard diet for ordinary labor pretty much as follows: —

Albuminoids	4.2 oz.
Fat	1.6 oz.
Carbo-hydrates	18.7 oz.
Mineral matters	1.0 oz.

It appears, therefore, that it would require about six of the sixpenny dinners to support a man during a day's hard labor. — *Medical Times and Gazette*, May 24, 1884, page 712.

phenomena, unconnected with sensible organic alterations, but characterized by neurotic and functional symptoms easily magnified by the patient and overtreated by the physician.

The consequences of an insufficient dietary are most frequently exemplified in young people, of both sexes, growing school children, boys fitting for college, *débutantes* in society, young mothers of families, seamstresses, shop girls, etc.; and although they also appear at other periods of life, and under other circumstances than those which have been enumerated, it is during the years of adolescence that the utilization of feeding has its supreme value and its prophylactic and curative effects, as a therapeutic method, are most easily obtained. Sir Andrew Clark, Mr. Grailly Hewett, Mr. Clifford Allbutt, and others who have described the ailments which follow inadequate alimentation, have especially urged the necessity for greater attention to the question of diet in the bringing up of families.

The underfed constitute so considerable a class that a large part of medical practice is devoted to attempts at satisfying their importunate demands for "something which shall make them feel better." To attack with drugs symptoms which are daily regenerated by starvation is labor in vain, so long as that condition is permitted to exist. But if the famished tissues of those who say they are not sick, and there is nothing the matter with them, only that they "don't feel well," and "cannot eat," be permeated with the fat which is so often loathed in food, — if veins be filled with a more bounteous supply of blood, and if out-door air be made attainable without the expenditure of an already slender supply of strength, — their bodily functions will take on renewed vigor and be reanimated from better life-giving resources, force will be stored up, energy will be developed, and innumerable discomforts evicted. The futile use of iron, quinine, bitters, elixirs, and other so-called "tonics," either when self prescribed or methodically directed by physicians, and the insuccess of medicines, as a rule, to relieve the wearisome complaints daily listened to from persons whose mode of living is an injustice to themselves, do not always serve as a reminder that suitable nutriment, in some form or other, is the only real "tonic," and that its methodical consumption can alone relieve the protean afflictions of many, if not most, of these querulous supplicants. To say to them in a vague and general way that a nourishing diet should be taken, and that anxiety and overwork are to be avoided, is to give weak advice. The most rigid and literal obedience to fixed and precise rules in regard to the quantity and character of their food and the times of taking it — in fact, the carrying out of a process of "stuffing," practiced at short intervals of time, without regard to appetite and pushed to the stomach's maximum capacity of digestion — is necessary to extricate them from their deplorable situation.

It is not my purpose to describe in detail the ailments and functional irregularities which are successfully dealt with by dietary treatment, but to make some criticisms on prevalent habits of eating, to offer certain practical suggestions in regard to methods of improving them, and a few homely remarks on the extent to which feeding beyond inclination may be advantageously pushed, and the kinds of food, and its adjuncts, by which its effective adoption may be promoted.

The theoretical standard of a full ration has been given. The conventional standard, however, is an unsettled one. The statement that a person eats as much as other members of his or her family may mean a great deal or nothing, for there are large and small eaters both by habit as well as by example, and there can be no criterion of the amount proper to be eaten under given circumstances except that which is determined by a physician's judgment. This amount, as has been said, should not only be specified exactly, but its consumption insured, and nothing but precise and positive evidence accepted in regard to the fulfillment of the specifications given.

To secure a constant and sufficient conversion of food material by those who are or have been insufficiently fed vigilant supervision is often requisite. The personal influence which accomplishes this is a variable possession. Some persons can win obedience where others might capitulate, and will exhibit a persistency in carrying out their suggestions which makes successful feeding a certainty when more lenient and compromising tactics would fail. Enfeebled subjects, especially women, often feel a great satisfaction in being controlled, and in being led, lifted, pushed by a strong will. With such individuals resolute oversight tells. That which they say, in regard to eating, they "cannot do" they are made to do. When they think they "do their best" they are compelled to do more and better, and an assertion that they will "try" to eat is counterbalanced by a determination that they shall succeed. No symptom of the feebleness which results from being underfed is more characteristic of the condition than the almost invariable obstinacy of its subjects to accept advice which suggests an increase in their consumption of nutriment, and no steps in securing a mutual understanding between physician and patient are so difficult as those directed to overcoming the dogged resolution and pertinacity which are manifested in this respect.

As a stomach may become over-distended and permanently dilated by long gluttony or by the accumulated ingesta which a slow and feeble peristalsis refuses to move on, so may it also become contracted from the habitual want of sufficient victualing, sometimes to such a degree that the introduction of enough food can only be accomplished after the gradual dilatation of its receptacle. This may be effected by increasing the frequency of meals. The custom, common in this country, of leaving a long interval between them is the reverse of that desirable for those who require extra feeding. The ordinary European arrangement adopts a system which is worthy of imitation, a "little and often" being the motto of the eater. It is useless to attempt too much at one time. The stomach conforms slowly, and rebels at a certain limit, but a brief respite and a short intermission put it in a less antagonistic attitude. If, for the reasons given, or from mere disinclination, two meals have been all which the subject under treatment declares can be "got down," as is often the case, then three must be taken or the time between successive feedings shortened to two hours, according to the aggregate amount of nourishment intended to be given and the readiness with which its forced consumption is effected. It is an advantage, therefore, that certain periods of the day, not precisely fixed, but approximative, should be established as meal times. For instance, before rising, at the usual breakfast hour, in the middle of the forenoon, at the accus-

tomed luncheon, in the middle of the afternoon, at the regular dinner, and on going to bed.

It is a common impression that to take food immediately before going to bed and to sleep is unwise. Such a suggestion is answered by a reminder that the instinct of animals prompts them to sleep as soon as they have eaten; and in summer an after-dinner nap, especially when that meal is taken at midday, is a luxury indulged in by many. Neither darkness nor season of the year alters the conditions. If the ordinary hour of the evening meal is six or seven o'clock, and of the first morning meal seven or eight o'clock, an interval of twelve hours, or more, elapses without food, and for persons whose nutrition is at fault this is altogether too long a period for fasting. That such an interval without food is permitted explains many a restless night, and much of the head and backache, and the languid, half-rested condition on rising, which is accompanied by no appetite for breakfast. This meal itself often dissipates these sensations. It is, therefore, desirable, if not essential, when nutriment is to be crowded, that the last thing before going to bed should be the taking of food. Sleeplessness is often caused by starvation, and a tumbler of milk, if drank in the middle of the night, will often put people to sleep when hypnotics would fail of their purpose.[1] Food before rising is an equally important expedient. It supplies strength for bathing and dressing, laborious and wearisome tasks for the underfed, and is a better morning "pick-me-up" than any hackneyed "tonic."

That the particular food is alleged to be unpalatable, or the hour at which it is to be taken inconvenient, is of no importance. Indeed, it sometimes lends a helping hand to have each mouthful considered the equivalent of a dose of medicine. A tablespoonful of cod-liver oil is often taken regularly and amiably when even the smallest quantity of some inviting delicacy will not be swallowed. It is a matter of observation, says Mr. Francis Galton, "that well-washed and combed domestic pets grow dull. They miss the stimulus of fleas." The energy required to dispose of that which is disagreeable is often a discipline of great service to certain classes of persons. Their faculties need to be whipped and spurred to prevent them from perishing by disuse, and the degree of vigor capable of being generated is often proportionate to the amount of coercion to which they are subjected.

The rugged way, however, may be smoothed by various procedures, and need not be made unnecessarily hard to travel. It is helped by selecting food containing the most nourishment and the least bulk, and which is easiest to swallow after a minimum of mastication, or without any. The culinary art facilitates the ingestion as well as the digestion of meats, which, without its cajolery, might be tough and uninviting. Skillful feeding by a nurse who recognizes the art which may be exhibited in coaxing food into the stomach is often of advantage. Food thus administered must be introduced in large mouthfuls. Every gourmet knows how necessary this is for the satisfaction of the palate, and the correctness of the fact is substantiated by reason and by analogy. Well-shaped, wisely-seasoned, large morsels make a relishing and appetizing mouthful, inviting repetition. In divided bits they quickly satiate or excite repugnance. By this epicurean method the stomach is rapidly and persuasively charged with a sufficient supply of nourishment, as it never can be by the feeble pickings of an apathetic eater. *L'appetit vient en mangeant* is a paradoxical adage constantly verified. Not only mere disinclination to eat is often successfully overcome by persistent feeding, but a liking for, and dependence upon, full and hearty meals is established, and, what is more, retained.

In cases where food is urgently called for its artificial introduction is an easy and beneficial manœuvre. It does not require a stomach tube, and has but little resemblance to the procedure resorted to with the insane. It may be practiced with insignificant discomfort by means of a soft rubber catheter, not exceeding a No. 12 in size, fitted to a small glass tunnel, into which the nutriment is poured, or it may be sent through the tube by a Davidson's syringe. The catheter need enter but a short distance into the œsophagus. If no resistance be offered the operation can be performed by almost any one, even by the patient himself. Milk, cream, broth, eggs, and homogenous liquids are thus readily deposited, and to the desired extent, in the stomachs of those disinclined to eat.

The number of females, especially those who "do their own work," whose food consists almost wholly of bread and tea, is very large. How inadequately they are nourished is shown by the statement that, in order to get the required amount of aliment, persons who eat nothing else must consume about four pounds of bread. As this is so much more than any one can dispose of with comfort, the practice of eating butter with bread is almost universal. This not only meets the necessity for a heat-producing, non-nitrogenous food, but the unattractive character of dry bread as an eatable is compensated for by the relish of a savory addition. In proportion as the use of butter is increased the requisite quantity of bread may be decreased. To eat "more butter than bread" should not therefore be the reproach to growing children which it is often made, and the large amount of the former which may be profitably disposed of by the underfed, without "disturbing their stomachs," is not surprising if the process by which oleaginous substances are taken into the system is recalled. "Fat, butter, and oily matter in general require no digestion, the emulsion into which they are mechanically converted, chiefly by the pancreatic and duodenal secretions, passes (almost directly) into the general circulation of the blood."[2] For reasons similar to those which make cream and butter such useful articles of diet, and because the habitual food of insufficient eaters is so lacking in fatty matter, cod-liver oil has acquired its well-deserved place among therapeutic and alimentary agents.

The tendency of those whose appetite is deficient to lay great stress upon their readiness to take food which does not require mastication makes them willing consumers of soup. And yet of all articles entering into the common dietary soups are perhaps the most deceptive, and certainly the most important to discountenance with the underfed. They fill up the stomach at the expense of solid, "staying" nourishment, and contain so little in the way of sustenance that they are therapeutically almost worthless. As a rule they are but some form of meat tea, and are now known to have a food value not unlike that which urine

[1] It should be borne in mind that a full bladder is a frequent cause of early morning wakefulness. Rising and passing water will often send restless sleepers back to bed for a refreshing nap, which without relief from this source of reflex irritation would not have occurred.

[2] Church, p. 36.

would possess, were it drank, and which they resemble chemically.[1] "They may have on the system a stimulant action somewhat analogous to theine. They may render more prompt and efficacious the assimilation of any wholesome food with which they may be associated, and they may even give so effective a fillip to an exhausted system as to enable it to dispense for a time with real food, but it is clear that they must not be looked to for direct nutrition."[2] The established use of *bouillon* at lunches and "Germans," and of a "clear soup" at the commencement of dinner, is thus accounted for; and it is only in a sense, such as has just been indicated, that the Crimean saying, "Soup makes a soldier," has any justification in fact.

Broths, however, that is, soups which contain large quantities of solid matter, disintegrated meat,[3] vegetables, macaroni, vermicelli, *pâte d'Italie*, rice, barley, sago, tapioca, etc., are often, and in proportion to the consistency thus given, excellent alimentation. They are palatable and easily consumed in considerable quantities at a time. *Soupe à la Reine*, *purée de gibier*, various vegetable *purées*, chowder of fish, *bisques* of oyster, clam, lobster, are illustrations of the perfection of this kind of cookery. That they may be what is sometimes called "rich" is no objection. The digestive powers of the underfed are usually good, though the owners of them may not think so. They are apt to be active and ravenous even if the appetite is not.

Notwithstanding its capacity to digest there is, invariably, something repulsive to an insensible stomach in what are conventionally called "roasted joints." This antipathy, together with considerations of convenience as regards the size of portions to be cooked, makes it almost imperative for protesting but frequent eaters that meats should be either broiled or stewed; and steaks of various kinds, chops, cutlets, chicken, game, some kinds of fish, and shell fish, become, therefore, the only really available resources of the caterer for an ill-ordered appetite. And yet no more difficult undertaking can be given non-hungry patients than that of eating beefsteak. Apart from its somewhat uncertain quality nothing requires more mastication, and the class named always declare that there is no item of food of which they are already more "tired." Any other variety of meat, mutton, veal, venison, etc., cooked in the form of steak, is more readily eaten. The short, compact fibre of mutton chops, especially those from the loin, makes them less likely than beefsteak to be badly cooked, and far easier to be consumed. Well selected, carefully-cut lamb chops, in their proper season, are a delicacy of the highest order, and rarely fail to be appreciated by the most benumbed eater.

Meats stewed, or semi-stewed, and then partially browned in the oven (braised, as it is called in the language of cookery) are attractive and submissive preparations, and this method of cooking is an excellent one for purveying small portions of animal food. In the various forms and denominations of stewing and braising the *cordon bleu* finds scope for the highest aspirations of culinary art.[4] They impart an appetizing flavor to viands cooked to extreme tenderness, the perfection of these methods being found in their application to sweetbread, a costly luxury, but an article which, by its slight demand for mastication and its nutritious qualities, is peculiarly adapted to the requirements of an invalid eater. Others of the viscera besides the pancreas and the thymus gland, namely, the brains, the liver, the kidneys, the testicles of lambs, successfully lend themselves to this process of cookery, and, like calves' heads, pigs' feet, and sheep's tongues, are converted into delicate and easily assimilated nutriment for those who are ignorant of, or can overcome, the associations which they suggest.

Of various mechanical processes available for rendering food easily eaten preparatory mincing offers great advantages, and is particularly applicable to chicken and veal. A common and attractive method of serving both in the form of minced meat is that of *croquettes*. I am at a loss to know why veal is so often proscribed rather than prescribed. Its chief defect is in being a lean meat, containing more water and less fat than mutton or beef, and consequently of subordinate nutritious value. It is, however, the standard meat of France, as beef is of England, and properly chosen veal, from large calves, is open to no dietetic objection which I am aware of except the difficulty of cooking it well. It is not less digestible than other young meats, and if occasionally "poisonous" it becomes so from decomposition, which, in the season of its abundance, more readily takes place from keeping, or changes in the weather, than is the case with meats of maturer growth. But this, like poisoning by partridges which have been too long kept in winter time, is an inexcusable accident.

In spite of the somewhat flippant assertion of a justly distinguished medical writer "that there is a growing incapacity to digest fat which is truly alarming," I do not hesitate to assert that of all the modes in which minced meat may be presented the calumniated and much-libeled sausage is, in winter time, one of the most useful and successful articles for frequent feeding. Lean and fat meats, more digestible together than separately, are discriminately mixed in the compact and appetizing form of this ubiquitous and popular comestible, the sole secret of whose easy digestion is that it should not be eaten except when it has become thoroughly cold after cooking. Bread and butter can be tolerated with complete immunity when hot buttered toast would provoke exasperating dyspepsia, and it is exactly thus that sausage cold stands in relation to that which is served hot. Presenting the albuminates and fat in an economical, savory form, easily obtained and made ready for consumption, sausage, in some countries, might almost be said to have become a national food, and it offers to the fastidious or indifferent eater an article of diet from which great benefit may be derived. A trial of this stigmatized edible will be followed by a ready recognition of its alimentary value in the class of cases under consideration.

As has been remarked already, food to be taken outside the conventional meal hours must be of a kind

[1] An old and essential custom prescribed recently-passed urine at the completion of every case of labor. Such a practice, it would seem, was not altogether absurd. I can myself recall an instance when this draught was administered after her confinement, as a matter of course, to the wife of an eminent medical gentleman, at that time connected with Harvard University.

[2] T. Twining, Familiar Lessons on Food and Nutrition, London, 1882, page 212.

[3] The meat from which soup is made, allowed to become cold, should be pounded to a paste in a mortar, and then returned to the soup. Veal, pigeon, and rabbit are especially adapted to this procedure. "French" cooks prefer to make "chicken broth" from rabbit.

[4] The details of braising and other refined culinary processes are feelingly particularised by Sir Henry Thompson, in Food and Feeding, third edition. London: 1884.

easily obtained anywhere, readily "kept in the house," and which does not demand preparation or delay. Few persons can command the services of a "professed cook," or of a good "plain" cook, or have either at their disposal every two hours in the day. The practical articles of diet which meet these restricted requirements of convenience are few, and of these the chief in importance are eggs, milk, cream, butter, and bread.

"Raw albumen is one of the most digestible of foods; coagulated, it is comparatively indigestible."[1] Eggs to be easily digested must be eaten uncooked, since albumen under prolonged heat acquires progressive degrees of toughness.[2] When cooked, buttered, salted, and peppered they are soon tired of as articles of food, and alleged to be "bilious." Cooking, moreover, involves waiting and preparation. An uncooked egg is always ready and at hand, is clean to be kept anywhere, and scarcely needs to be broken into a glass. With a little knack it may be swallowed direct from the shell, as most persons know if in childhood they have had access to country barns. A raw egg weighs from two to two and a quarter ounces, and is said to contain about the same flesh-forming and heat-giving material as an equal amount of butcher's meat.[3] It offers in perfection the quickest and neatest mode of taking a large equivalent of substantial and nutritious food at a swallow. Every bar-room realizes this, and supplies its counter with a bowl of eggs. The steady drinker, who has eaten nothing for breakfast and has no appetite, but knows the injurious effect of a drink on his empty stomach, can crack an egg, quickly dispose of it, and justify himself for an early dram. Even "soda shops" appreciate their value, and dispense them with lemonades and phosphates. Beaten-up eggs are the certain provocative of dyspepsia. When subjected to this process with the infinite pains taking of an attentive friend or nurse an inviting draught of creamy froth is brought to the unfortunate recipient, — a tumbler full of air, which has been introduced in the largest possible amount to a given quantity of egg, milk, wine, sugar, and nutmeg, — than which nothing could be better devised to promote indigestion, abominable eructations, and the most uncomfortable flatulence or acidity. Every beer drinker has the good sense to blow off the "head" of his mug of beer, or to wait patiently for the froth to subside, before he imbibes the draught; and if crotchety persons will not learn the trick of swallowing an egg whole, they can compromise the difficulty by slowly stirring the white and the yolk, which may be thus mixed together and made to seem a less revolting dose without the incorporation of air by beating. Taken as medicine, and looked upon as such, eggs are at least equally palatable with cod-liver oil, for which they offer an equivalent substitute, adapted to winter or summer, as the latter hardly is, and are far more readily digested. There is no limit to the number which may be taken with advantage continuously and for months at a time. Eighteen eggs are required to furnish the flesh-forming materials and other nutrients sufficient for the various needs of an adult man in one day. No more striking illustration of their concentrated food value, or a better proof of its general appreciation, can be given than the statement that during the first quarter of 1876, in Great Britain, the consumption of eggs reached the enormous number of seventeen and a quarter millions.[4] Fifteen millions were imported into this country from Europe in the year 1883. It is but fair, however, to remember that a vast number of eggs are used in the arts, especially photography, and in manufacturing processes.

Milk and cream are convenient and therefore important and desirable articles of food. It is a common assertion of patients that milk "always disagrees with them," — that they have "never been able to take it." This statement, which, as a rule, may safely be attributed to mere prejudice, is also in some cases a true one, simply for the reason that the milk is drank too rapidly, or because it is not rich enough, an easy remedy being to take the given quantity more slowly, or to increase by addition the amount of cream which the milk naturally possesses, the trouble being due, in the first instance, to the fact that a large and solid cheese curd is suddenly formed in the stomach by the rapidity with which the milk is deposited in that organ, and in the second, to the hardness of the casein derived from milk with an insufficient percentage of cream, which is always inconstant in amount (varying between ten and fifteen per cent.) or in composition, the water alone ranging from forty-five to sixty-five per cent.[5] Milk is often too poor, but never too rich, for purposes of enforced nutrition, and the fact is incontrovertible that it is the model food for digestibility.[6] By adding cream to milk the amount of fat is increased and the curd is softened; and its digestion can be still further facilitated by the disintegration of its coagula, accomplished by crumbling into it bread, cracker, etc., or by the addition of a small amount of cooked meal or flour. By this latter means cold milk is made warm, which gives it an increased efficacy. This end may also be attained and the distastefulness of warm milk removed by flavoring it with the preparations of cocoa, weak coffee, or some of the inert substitutes for the latter, sold by grocers, the best of which, it has seemed to me, is known as "new era coffee," consisting simply of roasted and ground wheat. But, as hot milk demands a certain amount of trouble, cold milk alone, or with bread broken into it is, after all, the only practical resource so far as its use for frequent nutriment is concerned; and two quarts of milk, or three pints of milk and one pint of cream, are not more than the minimum quantity desirable for ingestion in twenty-four hours. Clear cream may be administered in doses of a wine-glassful after each meal, as any other medicine might be, and a great deal can be disposed of by eating it liberally added to cooked fruit and various dessert dishes. *Blanc mange*, Italian cream, and the various forms in which many delicate farinaceous articles are cooked, may thus be made more eatable through the zest given them by this accompaniment. There is a great difference in the palatableness as well as digestibility of cream which is obtained from milk by centrifugal force, as is largely done for the market, and that which is skimmed after

[1] Twining, p. 184.

[2] Eggs should not be cooked by boiling but by placing them in hot water, and allowing them to remain there from seven to ten minutes.

[6] The analysis of "market" milk sold in Philadelphia and New York is as follows: —

Water	87.7 per cent.
Total solids	12 3 per cent.
Total solids, not fat	8.48 per cent.
Fat	3.75 per cent.
Milk sugar	4.42 per cent.
Albuminoids	3.42 per cent.
Ash	0.64 per cent.

A. R. Leeds, Medical News, July 21, 1883.

"setting." This distinction should be borne in mind in prescribing cream which is to be taken uncooked. The last-named product is by far the most desirable article.

Very few patients, especially women, drink a sufficiency of water to maintain their health or an adequate nutrition. Water is an important constituent of food; is, indeed, the carrier of food into and through the system, and forms more than two thirds of the whole body. Neglect to keep up the supply of water leads to a diminution in the quantity of blood, and lessens the body's strength.[1] When it is remembered that there are daily eliminated from eighteen to thirty-two ounces of water from the skin by perspiration, eleven ounces from the lungs, and fifty ounces from the kidneys, it is easy to see that the amount consumed by many persons falls short of the demand, and that their bodies must be insufficiently supplied with the requisite degree of moisture; some sixty-six ounces of water alone and in tea, coffee, beer, etc., being required for a daily supply over and above that which is contained in the solid food of a full ration to make good the average regular waste.[2] The constipation which is so common in ill-nourished persons is largely due to a want of liquid in the intestinal canal. This, therefore, will be ameliorated by the free use of water, as is also the constipating tendency of milk which is sometimes complained of, the curds being liquefied and reduced in size, and thereby made more readily digestible. Its effect on hardened fæcal masses or accumulated mucus in the intestines is equally obvious, and explains in part the intention as well as the success of the hot-water craze at present so popular.[3]

The underfed are benefited, and the process of feeding is helped, by alcohol. But the amount of alcohol which such persons may take as a food adjunct with advantage is very small. The cumulative effects of a medicinal dose at stated intervals are of greater utility than the more instant result of a larger allowance swallowed in a single drink. A measure of alcohol which produces an effect quickly, that is, which flushes the face, or exhilarates, as a sherry-glass of wine does with most females, for instance, is a toxic dose, and will be followed by reaction. It is a quantity short of this which is allowable. A teaspoonful, or at most a dessertspoonful, three or four times a day, is usually as much as can be borne without such sequelæ as are above alluded to. Spirits serve their purpose better than wine, for the reason that the relative quantity of alcohol administered is more measurable. Wines vary in strength; spirits are comparatively uniform. Tinctures even, or elixirs, may be given when spirits are objected to either on principle or from prejudice. In any case there should be a large dilution with water, as a more gradually stimulating effect is thus produced. Alcoholic medicines ought never to be taken on an empty stomach.[4]

The subject of bathing, incidentally alluded to, leads me to call attention to the fact that cold baths chill down the feeble circulation of the badly nourished, and provoke a physical torpor which is obstructive to the processes of nutrition. They drive the blood from the surface of the body in upon vascular organs, whose circulation is already sluggish from general weakness. They thus produce discomforts which aggravate existing languor, and enhance the feeling that food and drink ought not to and therefore cannot be taken. A bath described as one "from which the chill has been taken" is too cold for subjects under medical advice who are in need of extra feeding. Great pains should be taken to discountenance everything which reduces the bodily heat, and employments or amusements which in any sense tax the strength ought to be abandoned when a forced diet is attempted. Even ordinary exercise is often objectionable, and its complete discontinuance sometimes so important that confinement to bed is a necessity. Those who raise animals are practically made aware that a restless disposition is fatal to successful growth in vigor and flesh. The truthfulness of this observation is equally apparent with human beings who need "building up" in the literal sense of these remarks.

Mere fattening is not the object of full feeding, but it is to a certain extent its necessary accompaniment. The motive of the measure, as has already been stated, is to add to the quantity and quality of the blood, and it is hardly possible for an individual to grow fat without a decided increase in the volume of his blood. Weighing at stated intervals is therefore an important procedure, and there is no other way to make sure that the subjects of treatment are sufficiently well fed to gain blood. Persons who put on fat rarely fail to improve in color; their comfort is enhanced; warmth of body is gained, in itself no slight improvement; the pulse becomes fuller; the cheeks grow redder; the spirits are raised; the general mien becomes brighter; and these phenomena are explainable only by admitting that there has been an accession to their stock of blood. The scales thus become a thermometer of improving health and strength, by the aid of which the physician measures the progressive results of his regimen. Like the "pass-book" used at banks, they reveal in a ready and serviceable way the healthful standing of an individual, the relation of his resources to the wear and tear checks which he is continually drawing, and whether his account is nearly or quite overdrawn or superfluously plethoric. They ought not to be put into requisition too frequently, and only when there is reason to think that an encouraging increase of weight has taken place. This should manifest itself soon after systematic feeding is begun, and continue at the rate of two pounds a week, or not less than one pound, so long as improvement seems desirable, or until a weight has been reached the minimum of which shall be equivalent to two pounds for each inch of stature.

Experience and observation have universally confirmed the expediency of a heartier and more system-

[1] The characteristic thirst which attends great and sudden losses of blood is a symptom of interest in this connection.

Some valuable comments on the therapeutic uses of water, by Mr. Lauder Brunton, may be found in the Practitioner, May, 1884.

[2] Church, page 51.

[3] There was perhaps more common sense than Martin Chuzzlewit supposed in the American habit, prevalent when people lived more frugally, and went to bed with empty stomachs oftener than nowadays, which he noticed in his fellow boarders at Mrs. Pawkins', "who, after taking long pulls from a great white water jug upon the sideboard, and lingering with a kind of hideous fascination near the brass spittoons, lounged heavily to bed." Water drinking was indulged in thirty years ago more than at present, and in the half-starved existence which bred the lank and conventional type of American in those days, I cannot but believe that the comfort and well being of the then living community were greatly promoted.

[4] There is much pragmatical talk about "pure liquors," and the difficulty of obtaining them. It may be questioned whether alcohol and water, except for an educated and fastidious palate, is not as wholesome for medical uses as any high cost wine or spirit. Noxious impurities, when they exist, are usually owing to imperfect distillation, or lack of age, rather than to deliberate "doctoring."

atized diet than recently prevailed. Its utilitarian advantages are publicly recognized. Within twenty years the rations of armies, of institutions, charitable, penal, and medical, have been liberally increased. Family habits in regard to eating, since the flush times of the Civil War, have greatly changed, and the large allowance of food requisite for the maintenance of a sound health can scarcely be exaggerated in any statement of its details. In the application of this accepted dogma to special and personal cases there is much, however, still left to be desired.

I cannot better conclude this paper than by a paraphrase of Mr. Clifford Allbutt's words in his recent Gulstonian lecture,[1] wherein he observes, although not precisely in the language which follows, that: Under the benign and self-controlling influences of an amended nutrition the domestic atmosphere changes. Sore throats and trivial indispositions which once raised the frequent suggestion of a conflict with school, or a dinner, or an evening party, no longer present themselves as subjects for anxiety. Headaches and vague, transitory pains disappear. Ill temper, fretfulness, the fidgets, crying-spells, shrewishness, sleeplessness, listlessness vanish away, and the complaint of being "good for nothing" ceases to be made. By the building up of digestive resources a reserve of strength, which never before existed, is created, or a wasted one is restored, not merely for use on great occasions, but, by its wisely managed expenditure, to serve permanently for the silent work and equable running of vital machinery. Convince underfed invalids that no further defalcation of diet or new combination of drugs is needed; that, instead of waving dishes aside, like the physicians of Sancho Panza, they should be indulged in liberally, and they will find health within their reach; and by careful advances and the frequent repetition of small and highly nutritious meals realize that they can steadily eat their way upwards to a regenerated and tranquilized condition of body and mind.

SIX GENERIC DRUG MODIFICATIONS.[2]

BY HENRY M. FIELD, M. D.

Thirdly. Respecting the modifications which *age* introduces into medicinal action, space can be allowed for but brief illustration. Viewed from this stand-point, it would be difficult to find a greater contrast, throughout the entire range of commonly used medical substances, when prescribed to the young, than is presented by two narcotics which generally stand side by side in our classifications, namely, opium and belladonna. For, while the extreme type of susceptibility to the former is invariably presented by the infant, the extreme type of susceptibility to belladonna may well be found in the adult, provided it be a female of a certain temperament and physique. Again, children are but little susceptible to the toxic effects of quinia; indeed, some of Briquet's experiments would seem to show that they are capable of making a firmer stand against massive doses than adults even. *Per contra*, strychnia should be used, if prescribed to the young subject, with extreme caution. A number of severe and fatal cases of poisoning are on record from its use, hypodermically exhibited, as against paralysis sequential to diphtheria. Now farther investigation may lead to a modification of present views, but there is certainly much support for the position that the sympathetic nervous system is about equally susceptible to response in the young and adult. Materials which exert their chief physiological impression upon the body through the sympathetic — as belladonna does largely and quinia almost altogether — will be but little modified by the age of the subject, at least short of senility. Whereas materials which act primarily and chiefly through the cerebro-spinal axis, as does opium on its upper portion and strychnia on its lower tract, must, if given to the young, be closely watched and directed with great caution.[3]

In old age this principle must be differently interpreted, at least to an extent. The aged do not bear quinia well, and the remedy should be used with care. The operation of narcotics generally upon the aged has not received the attention it deserves; hyoscyamus, especially, so innocent with young children, should hardly be used at all on account of its tendency to produce a peculiar kind of mental aberration; a question not of the sympathetic, as we might have assumed, but of the brain. Chalybeates are measurably contra-indicated, so are emphatically saline cathartics. So are, to an extent, remedies which act upon the vaso-motor system and whose influence is conditioned upon the production of a modification of calibre of arterioles and capillaries, as in the case of chloral hydrates and the bromides.

The relation of remedies to increased arterial tension is a fact of quite constant consideration with the aged. The small dose of digitalis, to energize cardiac contraction, may be opportune and beneficent in action; a few drops too much, increasing the stringency of the already too tense arteriole, may be equally disastrous. Herein probably lies an explanation of the intolerance of the aged for the larger doses of quinine, — and of ergot as well, — their physiological influence upon the heart and circulation presenting analogy with that of digitalis. Still again, hereby is explained and justified the popular repute of sweet spirits of nitre in old age, possibly greater in England than in this country; Dr. Leach having shown that the influence of this mild and widely applicable remedy is procured through its power to relax arterial tension, — this by virtue of its nitrous acid, an ingredient and an influence which it possesses in common with nitro-glycerine, nitrite of amyl, and nitrite of sodium, — an influence greatly to be desired in the fever, and in the arrested skin or kidney function, of the aged subject.

Much of ingenious philosophizing has been devoted by certain writers, who are in love with the theory rather than the practice of therapeutics, to the problem presented by the great variety of modifications which infancy introduces into the action of medicine. I do not know that it has occurred to any one to apply to this question the philosophy of Asclepiades. And I have sometimes wondered, by the way, — if a momentary diver-

[1] Lancet, April 5, 1884, page 605.

[2] Continued from page 6.

[3] I cannot, however, agree with Albertini, who goes altogether too far in his statement that "children of fifteen months to five years of age may take, with impunity, doses of belladonna which would give rise to many symptoms of poisoning in adults." Only recently I had the misfortune seriously to alarm a mother for whose babe of six months I had ordered bellad. tincture for spasm of the bladder. Four drops, thrice repeated in the course of twelve hours, produced a scarlatinal rash over the entire body, wide dilatation of the pupils, and a considerable degree of excitement, alternating with something like stupor. That children will bear belladonna as well as adults is as much as it is safe to assume.

sion may be pardoned, — that some shrewd speculator in measures calculated to relieve those who suffer from the ills that flesh is heir to, observing the present craze of the community for the monstrous and the absurd in medicine, with whom the *omne ignotum pro magnifico* of homœopathy is an unfailing source of marvel and satisfaction; I have wondered that some such mountebank has not thought to erect a system of therapeutical statics and dynamics upon the cardinal principle of Asclepiades. For Asclepiades, although the author of the proverbial wisdom which we often quote, "cito, tuto ut jucunde," although the friend of Cicero, who speaks of him in his oration *De Oratore* as his personal friend and praises his skill in physic, was yet, in many things, a not unworthy predecessor of Hahnemann. Like Hahnemann, he affected to be wiser than, and to ridicule, all the fathers of medicine, and like Hahnemann he constructed his entire practice upon a preposterous proposition, — the one as preposterous in pathology as the other in therapeutics; both alike as captivating in the sound, to the untrained at least, as misleading in the sense, — to wit, that *all disease is due to obstruction of the primary atoms in their passage through the invisible pores.* This might serve us well in removing the difficulties of our present question, — if anything could be expected of remedies in such narrow and exiguous conflict, — for surely in infancy the atoms must be particularly "primary" and the pores particularly "invisible."

It were to be wished there was time to consider, practically, the modifications occasioned by infancy in the action of three prominent drugs, namely, opium, antimony, and mercury. Dr. Beck is the only authority, so far as I know, who has thought it worth while to write upon this subject, and his monograph was published some years ago. And yet this is a matter of very great concern to every practitioner. As respects opium, the young physician, unless he have some other guide than text-books and lecture-courses afford, and unless he be a man of exceptional caution, is in danger of gaining his early information through fatal experience. I can remember several young children that I believe I nearly killed by opium in the first years of my practice, and I went by the books. The fact that this drug acts upon the upper part of the spinal cord, below the brain, in the very young, when the inhibitory power of the brain over this portion of the nerve tract is at its minimum, and the fact, which Seguin appears to have established, that the "convulsibility" of the spinal cord ceases at about three years of age, suggest the importance of avoiding opium, so far as we may, till the child has passed this age.

Some one has said that the words *never* and *always* should not be used in connection with any medical subject. If there be an exception to this rule I think we have found it when we insist that *antimony should always be avoided, should never be used, in treating the very young.* Ipecac will do almost or quite as well, and ipecac is wholly safe. A prominent English writer, whose name I do not recall, writing ten to fifteen years ago, suggests as explanatory of the much greater fatality of croup in rural districts than in London the so much freer use by the country practitioner of antimony in treating the disease. It will be admitted that this drug is not as much used as formerly, but it is still employed altogether too much, that is, with the infant. Again, we insist our remarks are pertinent when it is remembered how commonly and freely the seductive "hive syrup" is still used in domestic practice, often with entire unconsciousness, even on the part of intelligent families, of its composition and its power.

Fourthly. The modification which may take place in a remedy by the *contemporaneous operation of another drug*, once fairly considered, would lead us to the discussion of combination, antagonism, etc., and all this, of course, must be set aside. A recent astute writer has well observed that there are few facts of pharmacodynamics, as, indeed, of practical therapeutics, of equal importance with that which has to do with the elimination of a medicine, adding that the old aphorism "*non agunt nisi soluta*" should rather read *non agunt nisi secreta.* Gubler has applied the term *vector* to a material which diverts another material from its usual avenue of elimination. Iodine, and probably bromine also, in combination with iron, is an illustration of the vector, the metal in this form or companionship being carried to the salivary glands, at least in a measure, a direction which no other chalybeate has been observed to take. Camphor is not eliminated by the kidneys, and would seem to have the power of carrying with itself, away from the kidneys, cantharides, which, otherwise, would seek this avenue of egress from the system; hence the influence of camphor as an antidote. "Camphor, in whatever doses taken by the stomach, is never passed in the urine" (Gubler), but monobromated camphor leaves the body by the kidneys, the bromine serving as vector.

Fifthly. The modifications impressed upon the action of a prominent material, for example, quinia or opium, *according as the influence* exerted is *physiological or therapeutical*, are more or less familiar to every tyro in medicine. Thus the most innocent substance can be converted for the occasion into the most lethal, as iron in certain states of disease. *Per contra*, the most powerful alterative becomes an emphatic tonic, corroborant, restorative; and if that which, at all other times, is a most potent and a universal disorganizer, does not directly serve in the rôle of hæmatosis and histogenesis, it does certainly stand as the essential vital catalytic, the *sine qua non*, without whose interposition these processes cannot, to the best estate, be resumed and continued. All this we observe of mercury in a certain stage of syphilis.

Every physician is familiar with the difference between the physiological and therapeutical action of alcohol. I have known a delicate woman, suddenly exsanguinated, consume a bottle of brandy in the course of a single night, and never once, as the saying is, feel it in her head; and yet, from previous experience, she could not probably have told the difference between cognac and sherry. Suddenly produced anæmia is one of the three conditions, — anæmia, spasm, pain, — and first among the three, which renders safe and beneficial large doses of opium; we have therapeutic for toxic impression, as in the teaspoonful doses and upwards ordered by Gouch and Hamilton in puerperal hæmorrhage.

An incident related in a sketch of the life of the late eminent orientalist and hero, Edward Henry Palmer, illustrates the principle, now being considered, in respect of alcohol. "One night, in 1866, he fell back on the sofa, and lay resting on his head and heels. The case closely resembled tetanus. Gradually he came round, and for months afterwards was compelled to drink enormous quantities of brandy, which produced no more effect on him than so much water. One night

he was in the rooms of a man who produced a bottle of whiskey. Palmer drank a glass of hot whiskey and water, and then leaned over and whispered to a friend, 'Take me away at once or I shall begin to talk about my rich uncles.' When he reached the bottom of the stairs he was so drunk he could not stand. 'You never before,' he said next day, 'saw a man who did right in thanking God that he was drunk. I was drunk last night, and now I know that I am quite well again.' There was no more drinking of brandy."

All that we know of the physiological action of the remedy would lead us to say that iodine never kills unless given with intent to kill or through ignorance or carelessness, equally culpable; and yet a brief course of iodine has been known to cause death. "True œdema of the glottis, as has been proven by the observations of Petitjean, may be produced by medicinal doses of iodide of potassium, *but only* in persons suffering from laryngeal affections before receiving the drug."[1] Here, through modification brought about by topical disease, the otherwise harmless and slight catarrh of the larynx, always liable to attend the physiological action of iodine, is magnified into a condition capable of causing speedy asphyxia.

Again, medicines may stand closely together as respects their physiological manifestations which have little in common when applied as remedies; physiologically nearly allied, therapeutically they touch at very few points or not at all. The phenomena of cinchonism and iodism are singularly alike, but cinchona belongs to the class of tonics, and iodine to the class of alteratives, while their medicinal indications are widely different. The physiological influence of ergot, digitalis, and quinia, as brought to bear upon the heart, stomach, and cerebral circulation, presents striking analogies, but not such as can be safely followed very far in practice, and of which, indeed, but little practical account can be made.

Once more, the physiological influence of a subordinate or obscure drug may tread closely upon that of a drug of the highest value, and yet the therapeutical power of the former be almost nil, or its range of medicinal influence very limited. Thus the excitation which follows apiol, in doses of two grammes and upwards, suggests at once the more characteristic phenomena of cinchonism as expressed by ringing in the ears, headache, titubation, and tendency to vertigo. The effluvia given forth by saffron possesses properties allied to those of the anæsthetics, producing, after a time, headache, muscular feebleness, a sort of indolence, torpor, and even stupor," etc., etc.[2] It goes without the saying that apiol would be a poor dependence in, perhaps, so much as one of the many conditions in which quinia is employed, while the aromatic odors of saffron would accomplish little towards the production of anæsthesia.

Sixthly and finally. Medicines are materially modified according to the *method and form of their use.* We have suggested changes caused (1) by the avenue through which the remedy reaches the system, (2) by its pharmaceutical status, and (3) by posology or dosage.

For a long time the constitutional effects of mercury were procured solely through inunction. It was not ventured to introduce into the interior of the body so powerful a poison. Our experience with the oleate, of the last few years, has partly revived the practice of former centuries, in less objectionable form, and assured us there was much to be said in its favor which had been long forgotten. Certain therapeutic modifications, certain wholly new resources, obtained through external and also through hypodermic exhibition, are of great value.

One fact, cautionary, respecting atomizing, and that of the cutaneous surface. "It has been proved by the investigations of Röhrig that finely pulverized, watery solutions of substances are taken up by the skin, while they are not absorbed if simply laid upon it. The experiments made upon this point, which were made with all possible precautions, showed that when watery solutions of the iodide or ferrocyanide of potash, for example, were applied to the skin in a finely divided condition one or the other of the drugs appeared in the urine. Animals could also be stupefied or brought into a paralytic condition by solutions of morphia or woorara exhibited in the same manner. This proves that the act of atomizing introduces substances into the body much more readily and in larger quantities than simple contact. Therefore the belief is fully justified that a very large portion of carbolic acid, employed in the form of spray, is absorbed by the skin or its sweat glands."[3] Such poisoning would be especially liable to obtain with children, who "naturally possess a much more limited power of resistance, since the surface of the skin occupied by the spray is much larger, in proportion to the whole surface of the body, than in adults, and, therefore, *cet. par.*, much more carbolic acid is taken into the system."

As respects modifications in medicinal action through rectal insertion there is need of farther research. We have at least corrected certain of the errors in vogue not many years ago. It has been proved that oils may be absorbed from this cavity, although this was, not long since, almost universally denied. We have repudiated the former false ratio which determined that the dose of opium, *per rectum*, should be threefold that *per os*. It may well be that children have been killed *secundum artem* by obedience to this rash tenet. Certain authorities, and Briquet prominently, assert of quinia that the dose by the rectum should be relatively small, as the activity of the remedy is relatively greater thus administered.

Space remains but for a remark concerning posologic modification, the contrast, to wit, always to be observed between the physiological and the toxic impression of any powerful remedy. This suggests allusion to the not infrequent charge, brought by the ignorant or prejudiced against physicians that they prescribe poisons for their patients; such triflers as amuse themselves with the inert inanities of homœopathy escaping this condemnation, and to them, in the present mood of the community, "it makes for righteousness." For although prepossession may expect some virtue from "*arsenicum*" or "*mercurius*" yet a very small modicum of common sense is prompt to declare that they can do no harm.

Now, gentlemen, it should be understood and insisted upon that we never prescribe poisons. We use morphia, strychnia, atropia as occasion calls, but we do not exhibit them in poisonous dose; they do not exert a poisonous action; they are not poisonous agents in our hands. There is as much difference — nay, there is more — in the operation of aconite as a

[1] Lewin.
[2] Gubler.
[3] Lewin.

remedy and aconite as a poison as there is in the toxic operation of aconite and digitalis, or the toxic operation of opium and nux vomica, of arsenic and mercury.

RECENT PROGRESS IN OTOLOGY.

BY J. ORNE GREEN, M. D.

DISEASES OF THE EAR IN TYPHOID FEVER.

BEZOLD[1] has made a clinical and pathological study of the aural complications of ileo-typhus, which is of great value from the large number of cases and from the many dissections. He distinguishes, as Schwartze has already done, three forms of ear disease as occurring in the course of typhoid fever: —

(1.) Deafness without symptoms of inflammation, and without objective appearances on the drum-membrane, and in the middle ear, which appears to be due to central changes.

(2.) Closure of the Eustachian tube, with the appearances of consecutive retraction of the drum-membrane.

(3.) Purulent inflammation of the middle ear (*a*) without rupture of the drum-membrane (*b*) with rupture of the drum-membrane and otorrhœa, otitis media purulenta acuta.

The first, so-called nervous deafness, is characterized exclusively by subjective symptoms, a variable deafness of moderate degree, and subjective buzzing. That such cases sometimes produce permanent impairment of the hearing is shown by a case which was carefully watched from beginning to end, and which never showed the slightest objective appearance of inflammation or retraction of the drum-membrane, and which was not accompanied by any severe pharyngeal catarrh.

Wunderlich, Griesinger, Murchison, and Liebermeister consider the ringing and buzzing partly symptoms of the prodromous period, partly of the beginning of the disease itself, but all agree that the deafness comes on only when it is evident that the general sensorium is affected. C. E. E. Hoffman says that these disturbances of hearing without objective symptoms, in severe cases of typhoid, appear very early in the disease, and often quite suddenly.

P. C. A. Louis,[2] gives the following figures, which are of interest in showing the proportions of patients with ear symptoms: Of thirty fatal cases eleven complained of buzzing, twenty of deafness, and two of pain in the ears. The buzzing began in four of these with the very first symptoms, in the others at various times, but nearer the beginning than the end of the disease. Of forty-five patients who were very ill but finally recovered nineteen had buzzing, thirty-three deafness, seven pain, and four discharge. The suppuration only appeared in the later stages of the disease, never before the twenty-second day. Of twenty-four lighter cases six had buzzing, five deafness, three pain, and one a purulent discharge, which began on the fourteenth day of the disease.

From his own observations Bezold agrees with these writers that subjective noises and a diminution of hearing, without objective appearances, belong to the earlier symptoms of abdominal typhus, and are of practical value for a differential diagnosis from many other acute general diseases. No statistics are given of the frequency of this form of ear affection.

Of the other two forms of ear disease, the catarrhal and purulent inflammations of the tympanum, fifty cases were found in 1243 typhoid cases examined between 1876 and 1880. Of these fifty cases but two, however, were of the simple catarrhal variety, while forty-eight were purulent inflammations of the tympanum, and Bezold gives the conclusion that in typhoid fever acute inflammations of the Eustachian tube are not more common than they are in healthy adults. The small number of cases placed under this second, catarrhal, division will be a surprise to those who have examined many typhoidal patients, but the explanation is found in the fact that Bezold classifies under this division distinct and undoubted tubal catarrh only, while cases of catarrhal inflammation of the tympanum proper, as they used to be called, are by him classified as acute inflammations of the tympanum, according to the recent nomenclature of Politzer.

Of 1243 typhoid cases examined, forty-eight, or four per cent., showed acute inflammation of the middle ear. Of these forty-one had perforation of the drum-membrane and otorrhœa, or 3.3 per cent. of all the cases examined.

While the nervous affections of the ear are found in the beginning or even in the prodromous period of the disease, the inflammations of the tympanum are first seen towards the end of the general disease, usually between the twenty-fifth and thirty-fifth day. In Bezold's cases only three began before the twentieth day, namely, on the ninth, the thirteenth, and the seventeenth day.

The acute inflammation is either slight, without rupture of the drum-membrane, or more severe with perforation of the membrane. In the former case, usually towards the end of the disease, moderate intermittent pain is complained of in the ear, with a little deafness, which latter may gradually increase to a marked degree. A diffuse injection is seen on the drum-membrane, most marked in the posterior upper quadrant, while the rest of the membrane appears opaque and grayish-white. Without the inflammation going on to any higher development this condition may remain for several weeks, and then, by a retrograde process, return to the normal. The appearances here are those of acute middle-ear catarrh, but a dissection of such a case, by Bezold, proved that the secretion, even in the beginning, was purulent.

The more severe variety was observed in thirty-six cases unilaterally, and in five bilaterally. The time of its appearance averaged between the fourth and fifth week. The appearances and symptoms are those of a more pronounced inflammation; the injection and swelling are more intense; buzzing, sometimes pulsating, is often present; the pain is more severe, and, even in the beginning of the disease, there is a decided sensitiveness to pressure over the mastoid process; fever is generally present, and the temperature raised until perforation of the membrane occurs. From the late period of the disease at which the ear trouble comes on Bezold considers, and with justice, that the increased fever is due to the inflammatory ear disease. Often in one and usually within a few days rupture of the membrana tympani occurs, and an abundant serous, or bloody serous, discharge, with which a few masses of pus are mixed, appears. As the result of the discharge maceration and a hyper-production of epi-

[1] Bezold, Ueber die Erkrankungen des Gehörorgans bei Ileotyphus. Archiv für Ohrenheilkunde, vol. xxi., p. 1.
[2] Das Typhöse Fieber, etc., Leipzig, 1842.

dermis takes place in the meatus, obscuring the view. The perforation is almost always located in the posterior half of the membrane. The secretion, in a few days, becomes muco-purulent, and may so remain for weeks and even months in spite of careful antiseptic treatment. Succulent polypoid growths may develop from the mucous membrane, and in several cases Bezold has seen white spots on the inflamed mucous membrane which suggested diphtheritic deposits. Very marked sensitiveness of the mastoid was found nineteen times in the forty-one cases, and in eleven of these this sensitiveness was found at the very beginning of the ear disease, while in eight it appeared from the second to the twelfth day, due, Bezold thinks, to inflammation of the mastoid cells as well as the mastoid antrum. In five of these nineteen cases there was external periostitis. The temperature in the milder cases often becomes normal after rupture of the drum-membrane, but in the severer cases it may show the great and irregular variations characteristic of pyæmia.

The extreme deafness sometimes met with in typhoidal suppuration of the tympanum is, Bezold says, greater than he has ever seen with spontaneous tympanic inflammation. In one case the deafness for speech was total for nineteen days, but at the same time bone-conduction for the tuning-fork was good.

The suppuration of the tympanic mucous membrane Bezold regards "as the natural healing process of the acute inflammation produced by a local infection. He regards it as the normal reaction of the mucous membrane to the inflammatory irritation which has reached that spot, and that it leads directly to healing in that thereby the infecting agent is eliminated from the tympanum." With this belief he limits therapeutic measures to preventing new infection and the decomposition of the secretion by using antiseptics, of which he prefers boracic acid, and by washing out the middle ear, preferably through the Eustachian catheter, as advised by Politzer.

The cause of the ear diseases in typhoid has been variously given. Griesinger goes so far as to refer even the purely nervous disturbances which occur in the beginning of the fever to catarrh of the Eustachian tube and tympanum, while Hoffmann and Troeltsch would only refer the secretory inflammations of the tympanum to an extension of inflammation upwards from the pharynx. Schwartze regards the tympanic inflammation as a purulent inflammation of the tympanic mucous membrane independent of closure of the Eustachian tube or pharyngeal disease. The question whether the specific typhoid germs find in the middle ear a favorable seat for their development, and act here as exciters of the inflammation, Bezold answers in the negative because of the marked absence of lymphatic tissue, and especially because the purulent tympanic inflammations, as has been said, only show themselves in the later stages of the general disease when it is fair to assume that the specific germs are already eliminated from the system.

The middle ear process may be the result of naso-pharyngeal disease in two ways, either by long-continued closure of the tube or by a direct extension of the catarrhal or diphtheritic disease of the pharynx, per continuitatem, into the tympanum. That a closure of the tube is the cause Bezold denies, for, during a year, he examined every typhoid patient frequently, and in no one of them could he find the recent retraction of the drum-membrane characteristic of closure of the tube, and yet many of these cases afterwards developed purulent tympanic inflammations. A direct extension of the inflammation from the pharynx, he thinks, may explain the lighter cases of ear disease, but wholly fails to explain the severe cases, for these begin quite suddenly, and are accompanied from the beginning by involvement of the mastoid cells. Dissections also prove that very often the inflammation is limited to the tympanum, and does not extend into the Eustachian tube, a condition which would not exist if the disease had extended along the tube from below. The secretion in the tympanum, at least in the majority of cases, is purulent from the very beginning both in the perforative and non-perforative forms.

Besides extension from the pharynx for the milder cases Bezold suggests two other causes of the tympanic inflammation, the entrance of septic material from decomposition of the naso-pharyngeal secretion, and possibly of small particles of food, and, secondly, emboli in the vessels of the tympanic mucous membrane from endocarditis and thrombus of the left side of the heart, or from masses of suppuration in the periphery. The former has not been proven, the latter was found in a case examined by Bezold in a branch of the arteria stylo-mastoidea, and although in this case the heart was not examined infarcts in the kidneys showed the existence of embolic material in the left heart. Trautmann also has found small emboli in the tympanic mucous membrane.

Reports of Societies.

PROCEEDINGS OF THE BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

E. M. BUCKINGHAM, M. D., SECRETARY.

JUNE 9, 1884. The President, DR. CHARLES D. HOMANS, in the chair.

DR. R. M. HODGES read a paper entitled

DIETETIC DELUSIONS; THEIR DELETERIOUS EFFECTS AND THEIR RECTIFICATION.[1]

DR. FRANCIS MINOT wished to make one or two suggestions called out by the paper. The temperature of food is often too high. Particularly is this the case with potatoes, and with tea and coffee, which are not uncommonly used when hot enough to interfere with digestion. Among the foods at once nutritious and palatable he gave a high rank to fresh condensed milk, which differs from the canned milk that is imported, and somewhat resembles the so-called boiled milk of the French cafés. This last is not really boiled, but is allowed to simmer and evaporate all night over the fire, preparatory to being served with coffee in the morning. The speaker had met with the difficulty described by Dr. Hodges in getting some women to eat. He believed that there are cases that can be successfully treated only by refusing to make another visit unless the prescribed quantity of food is taken. This course will probably succeed provided the patient has confidence in her attendant.

DR. R. T. EDES said that he thought there has already been some little reaction from the acceptance of Weir Mitchell's teaching about forced feeding in bed.

[1] See page 25 of this number of the JOURNAL.

Some cases do well with a less active treatment. He did not mean by this, however, to imply that the reader was accepting that treatment in full. He thought it a mistake to regard too carefully the chemical composition of food. To get the best results from food it must be palatable, and he was somewhat surprised that Dr. Hodges had not had a good word for mince pie. The speaker would hardly call malt extract a tonic, but rather considered it a food, although it does have diastatic qualities, and the question of the predigestion of food is sometimes important. He took the opportunity to speak of preparing milk by slowly adding dilute hydrochloric acid to it drop by drop while warm, stirring at the time. By this means the curd is broken up and becomes more digestible, while the taste is more agreeable to some people than other predigested foods.

DR. G. K. SABINE thought that the subject is very important, often more so than questions of drugs or exercise or of hygienic surroundings. Even bad air can be borne for a time by those who are well fed. The importance of good food is well seen in the country, where it is astonishing how poorly farmers live, and how underfeeding and overwork tell on the health of the women. It had occurred to the speaker that the hours of meals may have an influence on the drinking habit. A dinner at noon followed by a light supper leaves one empty and uncomfortable at night. A glass of whiskey will often relieve this feeling, while had a full meal been eaten in the evening the discomfort would probably not have existed. The value of eggs mentioned in the paper might perhaps be overestimated, as now and then they upset the stomach.

DR. H. C. HAVEN deprecated a too free use of meat in the dietary of *childhood*, and up to the seventh year would exclude it entirely, provided that the dietary was intelligently constructed, so as to furnish in other forms the proper amount of albuminoids. He believed that the old rule of meat once a day for children was much better than twice or thrice a day. In childhood, especially during the earlier years, when developmental changes are still most active, there is a relatively greater susceptibility to stimulants to the nervous system. Reflex action from the slightest irritants is a well-known phenomenon of infancy and childhood; and the salts or extractive matters in meat, which give to their solutions the stimulating qualities they possess, should be used with great caution, or, if nitrogen-containing food is otherwise furnished, dispensed with.

Dr. Haven believed this to be especially important in the cases of children who either had, or might be supposed to have, inherited the neurotic disposition. He had seen the "nervousness" of children, manifested by the symptoms of irritability, night terrors, or talking in the sleep habit, chorea, etc., disappear after exclusion of meat from the dietary.

If Americans *are* more "nervous" than the people of other nations, it behooves us to be especially careful of American children during the period of development of the nervous system.

He spoke of statistics quoted by Dr. Cannan in an article entitled Milk Diet in Childhood.[1] In an institution in New York, where for the past twenty-five years meat has been excluded from the dietary, even in the form of soup, the average number of inmates between three and eight years of age has been 110. In only nine of the twenty-five years has there any death occurred among these children. In these nine years the total number of deaths has been only twenty, or less than two per cent. of the inmates. The children are kept from three to twelve years, and are therefore under observation for a considerable time. These figures are certainly worthy of careful consideration.

[1] New York Medical Journal, vol. xxxix., No. 13.

DR. J. J. PUTNAM agreed with Dr. Haven, and stated that epileptics often do better without meat.

DR. HODGES said that while individuals may do well without it, yet that it is not the rule.

DR. J. C. WARREN referred to a recent book by Professor Erbstein on the Banting process, which shows that absolute abstinence from fat is needless, patients losing two or three pounds in a week while taking butter freely, but having their starchy food and sugar reduced. There is a limit to this, however, and *milk* is not allowed by Erbstein, possibly on account of its sugar.

DR. HODGES, in reply to Dr. J. J. Putnam, said that for fat anæmics he always tried exercise.

DR. MINOT thought that they were improved by forced exercise, and related some cases in support of his statement.

DR. J. B. AYER said that while it is true that milk disagrees with some people, yet by beginning with somewhat small quantities, and adding lime water or cream, the difficulty disappears.

DR. C. P. PUTNAM agreed with Dr. Haven that children ought not to have more than a limited quantity of meat. In them it produces dyspepsia. He has observed that when they get much of it at an early age the fæces assume a putrid odor different from that of the milk-fed child or the meat-eating adult, and he thinks this also should be taken as an indication that with them meat is not easily disposed of in the economy.

In adults, he thought the quantity of meat eaten should vary with the amount of exercise taken, and he spoke of constipation caused by milk. He also said that while sausages form, in some countries, a staple article of diet, yet that the Germans eat so much bread at the same time that that is with them the more important article of the two.

DR. SABINE said that the German sausages are made of one half beef and one half pork, less highly spiced than ours, and are boiled instead of fried. They can be bought in this city.

DR. BUCKINGHAM said that he, as well as Dr. Sabine, had met with people who could not eat eggs, and so many of them as to surprise him, considering the common opinion on the subject. It was fair to say, however, that he had not made the same distinction between cooked eggs and raw eggs that is made by Dr. Hodges. He agreed with Dr. Haven that up to five, six, or seven years milk should form the principal part of children's diet. It was his impression that children otherwise fed were more likely to have digestive disturbances. Children always like milk if they are encouraged to do so, or acquire a distaste if too early weaned from it, and this matter of liking may play an important part in disease even after childhood is passed.

— "Death owing to visitation of Providence under suspicious circumstances" is reported as a coroner's verdict in Munster.

MEDICAL ASSOCIATION OF THE COUNTY OF NEW YORK.

AT a meeting of the Association held June 16th, DR. J. LEWIS SMITH read a paper on

THE SUMMER DIARRHŒA OF CHILDREN.

Having remarked that it was gratifying to know that of late years the enormous mortality from this affection in large cities had been somewhat controlled in consequence of the measures adopted for this purpose by boards of health, he said that it still continued the great scourge of the community during the heated term, and proceeded to quote a number of statistics showing this, which were taken from the records of vital statistics of the city of New York.

The ætiology, he went on to say, depended on two principal factors, the one atmospheric and the other dietetic. In regard to the first, the prevalence of the affection corresponded closely with the increase of atmospheric heat, commencing in the month of May, and reaching its maximum during July and August. The fact that the mortality from it was greater in October (when the average temperature was lower) than in May, was explained by the circumstance that the deaths from it were among children who had contracted the disease in the summer and whose constitutions had finally yielded to its debilitating effects. Although the summer season was responsible for the wide-spread mortality from it, it was not easy to ascertain the precise elements to which this was due, since much the same degree of heat prevailed in the rural districts as in cities. It seemed altogether probable, however, that noxious effluvia constituted or contained the morbific agent or agents; and in support of this hypothesis Dr. Smith related a number of facts which had come under his personal observation. Murchison found that twenty out of twenty-five boys were attacked with diarrhœa which was excited by the emanations from an old drain near the school which they attended, and the purgative effect of impure air was well illustrated by the fact that medical students previously in good health were not infrequently attacked with diarrhœa as the result of working in the dissecting room.

In all large cities solid impurities were very numerous in the atmosphere, and this accounted in great part for the hazy cloud that could usually be seen hanging over cities and towns. Whether organic impurities giving rise to diarrhœa were organized or not was not yet definitely determined. A bacillus of cholera infantum, it was true, had been discovered; but whether it was a causative agent, or merely an incidental concomitant, was still an open question. He then referred to certain gases and gaseous combinations liable to be found in the air, which were supposed to have a distinct effect upon the bowels, and mentioned the sulphates as being among the most active chemical compounds in this respect. In the present state of our knowledge, we had to be content with saying that impure air was one of the great causes of infantile diarrhœa, without being able to state precisely in what manner it produced this effect.

This led, however, to the presumption that, in addition to heat, infectious germs constituted an important element in the ætiology; and the conditions existing in the summer in cities were certainly favorable to the development of low organisms. He then proceeded to describe the various circumstances characterizing the life in the crowded tenement-houses in New York, which were so productive of disease and death among the infantile population, and especially during the heated term.

Going on to speak of the dietetic factor in the causation of infantile diarrhœa, he remarked that in the large cities children under eight months of age, if bottle-fed, were almost invariably attacked by it in summer. In institutions it was a well-known fact that every bottle-fed infant under four months, and often under six months even, died at this season. But in addition to being bottle-fed the infants in the tenement-houses were very frequently allowed to have various kinds of fruit as well as the ordinary table fare of adults, so that it was no wonder that diarrhœa was prevalent among them.

Occasionally it happened that from continued ill health the milk of the mother became deteriorated, and no longer agreed with the infant, and although under ordinary circumstances breast-milk was incomparably the best diet, it thus became necessary to put it upon some other food, provided it was impossible to secure a wet-nurse for it. Cow's milk was, on the whole, the best substitute for mother's milk, but the milk that was obtainable in New York, especially by the poor, was often of such bad quality that it was exceedingly apt to disagree with the child. In New York improper feeding was quite sufficient to produce diarrhœa without the influence of atmospheric conditions, but with the two causes combined it was not to be wondered at that the infant mortality was so large during the summer months.

Having spoken of the better care now taken of foundlings, as compared with the former condition of affairs, when this class were intrusted to the care of pauper women in the almshouse on Blackwell's Island, and it was a very rare occurrence for one of these little waifs to reach an age of more than two months, Dr. Smith spoke of the supposed influence of dentition in the ætiology of summer diarrhœa, and expressed the opinion that this had nothing whatever to do with its causation. This, he thought, was proved by the fact that infants under three or four months (or before reaching the age of dentition) were even more liable to the affection than older ones in whom the process was taking place.

He passed over the portion of the paper describing the symptoms, except so far as to mention that in the great majority of cases the disease began very gradually, so that mothers were apt to neglect attending to it until the pathological process had reached a considerably advanced stage. There were, however, certain sudden and severe cases which were properly designated as cholera infantum, or choleriform diarrhœa, and which bore a striking resemblance to true Asiatic cholera. In no other disease except this was such a marked change in the appearance of the patient so quickly produced. In referring to the anatomical characters of the disease he stated his firm conviction that it was an inflammatory affection from the first, an opinion which was based on his own personal observations in a large number of autopsies. It was really an ileo-colitis, as it was in the ileum and colon that the lesions were principally, although not exclusively, found.

On account of the length of the paper he was obliged to omit the portions of it relating to diagnosis, prognosis, and preventive measures, and pass on to a

consideration of the curative treatment, which, he said, comprised four principal points. These were: (1) to give the best available food, (2) to supply the child with pure air, (3) to aid digestion, and (4) to use appropriate medicinal agents to check the diarrhœa. If the mother was not able to nurse her child and a wet-nurse could not be provided, it became the physician's duty to recommend some substitute for breast-milk. Cow's milk was universally conceded to be the best substitute for this; but, unfortunately, cow's milk in cities was extremely apt to be defective, and so likely itself to be one of the causes of diarrhœa. How to modify cow's milk so as to make it resemble human milk as closely as possible was one of the most valuable suggestions that emanated from an important congress of well-known German physicians interested in children's diseases, which was held in 1881, and this suggestion was, that peptonizing it had the effect of rendering the casein, which was the chief source of indigestion in the milk, readily digestible. In peptonized cow's milk it was found that the casein was in delicates flakes, instead of the hard masses in which it ordinarily existed in this fluid, and it was recommended that the process of peptonizing should be suspended as soon as the milk began to assume at all a bitter taste. In order to have the milk in the best possible condition for the child's use it was necessary to peptonize it in small quantities as required, and Dr. Smith then proceeded to describe the way in which it was now prepared at the New York Foundling Asylum, an institution with which he was connected: five grains of extractum pancreatis and ten grains of sodium bicarbonate being added to one gill of warm water and one pint of cow's milk. The liquid should be tasted frequently during the course of preparation, and as soon as it became in the slightest degree bitter the peptonizing should be arrested. This could be done either by heating the milk or by placing it on ice, and the latter he considered preferable, as this only suspended the process (which it was desirable should be renewed in the child's stomach), while the application of sufficient heat to arrest it had the effect of destroying the ferment. This peptonized milk was then to be further diluted, according to the age of the infant for whom it was intended.

Before the process of peptonizing was resorted to barley flour was frequently added to infant's food for the purpose of separating the cakes of casein found in cow's milk into smaller subdivisions, and this was probably the next best substitute. Liebig had been the pioneer in devising a physiological substitute for mother's milk, and by his process of converting starchy matters into grape sugar had conferred a substantial benefit. Having referred to the use of wheat flour and of malt extract in the preparation of the diet of infants and young children, he spoke in conclusion of several of the artificial foods now in use, omitting the part of the paper which was devoted to the medicinal treatment of summer diarrhœa.

DR. H. A. POOLER, of Goshen, N. Y., and PROFESSOR LEEDS, of the Stevens Institute, Hoboken, had been especially invited to participate in the discussion of Dr. Smith's paper. The former devoted his remarks principally to a consideration of the evils resulting from the adulteration of milk and its transportation from long distances, and to practical suggestions for securing a sufficient supply of pure milk produced within a comparatively short distance from the city. Through the efficient coöperation of the State Boards of Health of New York and New Jersey with the New York City Board of Health, however, much progress, he said, had already been made in the way of reform; so that within the last year or two the prevention of adulteration had reduced the supply of the city by about one hundred thousand quarts, and the milk was consequently of a much better quality. The result of this improvement, he thought, was shown in the fact that the mortality from diarrhœa was 3664 less in 1883 than in 1882. He also spoke of the importance of giving milk to young infants at the temperature of milk from the mother's breast, and in its preparation to add a sufficient amount of cream, since by diluting it with water in order to reduce the casein the quantity of fat was also proportionately reduced.

PROFESSOR LEEDS spoke first of the impurities in the atmosphere as shown by the analysis of rain-water, which in falling became impregnated with them. Thus he had found rain-water collected in Hoboken to be very much more impure than any of the water taken from the head-waters of a number of streams in Eastern Pennsylvania, which he had analyzed for the purpose of advising in the selection of a new water supply for the city of Philadelphia. It had been a matter of surprise to him that the medical profession had not provided itself with more definite information as regards the purity and impurity of the atmosphere under different conditions, and he thought that it would be an excellent thing if the Signal Service Bureau of the government would supplement its meteorological reports with reports of the proportion of oxygen, organic matters, etc., in the atmosphere.

As regards the matter of infant feeding, he was of the opinion that we were much nearer a practical solution of this important problem than had been deemed possible ten years ago. This had been indicated by Dr. Smith, who had rightly attributed great importance to the results of the conference of German physicians to which he had referred. All authorities were agreed that cow's milk was, on the whole, the best substitute for mother's milk, and the practical point was, therefore, to determine what was the best way of preparing it for the infant's use. We did not know at the present time, he said, precisely what the elements were which made up the so-called casein of cow's milk, it having been determined simply that this substance was coagulable by acids. We did know, however, that there was a difference in the percentage and in the character of the albuminoids and the fats found in cow's milk and in human milk, while the milk-sugar was the same in both. As Dr. Smith had mentioned, it had been demonstrated that the casein of cow's milk could be rendered similar to that of human milk by peptonizing it. As to the fat in human milk, it was not all appropriated, since about twelve per cent. of it, as a rule, could be found undigested in the fæces of the infant. It was, therefore, supplied in excess by nature. In cow's milk the average quantity of albuminoids was twice that found in human milk.

In the preparation of a substitute for the latter he would suggest that to a pint of good cow's milk one pint of water should be added. If to this mixture two ounces of cream and four hundred grains of milk-sugar were added the percentage constitution would approximate very closely that of mother's milk. If, furthermore, the insoluble casein of the cow's milk

were converted into soluble peptones by the action of extractum pancreatis, as recommended by Dr. Smith, it seemed to him that we should have a reliable substitute for the natural food of the infant, which would probably give satisfactory results if practically tested. The recent advances made in regard to this subject would, in the near future, he thought, work untold good in the reduction of the now enormous mortality among infants and young children.

At the conclusion of Professor Leeds' remarks DR. WILLIAM H. WELCH presented the specimens from a case of

PRIMARY TUBERCULOSIS OF THE GENITO-URINARY APPARATUS.

It seemed to begin in the left epididymis, which was enlarged, mostly in the globus major, the distended tubules being filled with cheesy matter. The left testicle was involved, as well as the corresponding *vas deferens*, and the caseous substance mentioned could be traced up to the situation of the seminal vesicles and prostate gland. In that position, behind the neck of the bladder, a tuberculous abscess having a cavity of the size of an orange was found, and this had completely destroyed the seminal vesicles, as well as the central portion of the prostate gland, while at one point it opened into the prostatic portion of the urethra. Miliary tubercles were found throughout the whole length of the urethra, as well as in the bladder. The left ureter was dilated and filled with the same cheesy matter as other portions of the genito-urinary tract, and the left kidney was also the seat of extensive tubercular disease. Dr. Welch supplemented his presentation of the specimens with some remarks on primary tuberculosis of the genito-urinary apparatus in general.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M. D., SECRETARY.

JANUARY 12, 1884.

DR. T. M. ROTCH, present by invitation, reported a case of Malformation of the Vagina closely simulating in its external appearances exstrophy of the bladder.

CASES OF PREGNANCY COMPLICATED WITH FIBROID TUMOR OF THE UTERUS.

DR. W. L. RICHARDSON reported two cases of Pregnancy Complicated with Fibroid Tumor of the Uterus.

CASE I. The patient was a stout married woman, twenty-seven years of age, whose general health had always been good: the catamenia had usually been regular and not profuse, lasting four to five days; but for a few months preceding pregnancy the flow had been rather light colored.

There was nothing especial noticed during pregnancy except that nausea was much more marked in the later than in the earlier months. There was no œdema. The urine contained a slight trace of albumen; but no casts were discovered.

The patient entered the Boston Lying-in Hospital for her first confinement.

The os dilated very slowly under chloral and ether.

After sixty hours the breech, the presenting part, began to descend, and in two hours it reached the perinæum, where it remained. After ten hours, as no advance was making, the fœtal heart beating 200 per minute, and the woman becoming much exhausted, the patient was etherized.

Examination showed that one foot was pressing against the symphysis pubis, preventing the advance: the foot was pressed up with difficulty. The conjugate diameter was found to be narrowed. The fillet was now tried, but could not be passed: finally a tape was passed around the thigh by means of a hard rubber catheter. The fillet was tied to the tape, and thus was drawn around the groin.

The body was extracted without much difficulty; but forceps were necessary for the aftercoming head: the child was still-born.

There was no hæmorrhage. The placenta was retained and had to be removed by the hand passed into the uterus. The patient was given a douche every six hours, and ergot twenty minims every three hours, with enough morphia to make her comfortable.

On the following day her temperature rose to 102° F., she was very nervous and excited, and complained of great pain in the abdomen, which was tympanitic and tender on pressure.

The catheter was necessary. The inner surface of the perinæum was black: iodoform was applied.

On the fourth day large sloughs were discovered which included most of the vaginal surface. She was given a douche every six hours followed by an iodoform spray. While the nurse was absent from the room the patient got out of bed.

On the sixth day she slept a great deal and when awake seemed in a dazed condition: she talked much in her sleep. When asked a question she repeated the answer several times. Bromide and chloral did not quiet her. The pulse had become much smaller, the lochia scanty and very foul: vaginal douche with iodoform every four hours.

On the seventh day the tongue was dry brown and cracked: the fundus of the uterus was still at the umbilicus: the vaginal walls were a mass of sloughs. The patient was taking several pints of nourishment daily: had an attack of urticaria.

On the ninth day, after several large dejections, she seemed somewhat brighter, but her mind was wandering and she was very restless and talkative.

The urine was dark brown, acid, specific gravity 1017 to 1021; indican increased, urophæin and urea normal, uric acid much increased; very slight trace of albumen. The sediment contained much uric acid, and an occasional blood globule and hyaline cast, the urine resembling that of renal hyperæmia of carbolic-acid poisoning. The iodoform was at once omitted, but was soon resumed though very sparingly.

For the next week the patient's general condition was much improved. The temperature and pulse both fell nearly to normal, she slept better, and was more rational. The vaginal discharge was very offensive; but the sloughs had nearly disappeared.

On the seventeenth day it was noticed that the vaginal discharges came away in gushes, were exceedingly foul, of a slaty color, and purulent in character: the fundus of the uterus was just below the umbilicus. The patient now became more restless and delirious, and her general condition was much worse, the temperature and pulse rising. Abdominal tenderness had about disappeared. Iron and malt were given.

On the twenty-second day she had two decided chills.

On the twenty-fifth, after much pain in back and abdomen, a large foul mass was discharged from the vagina, which Dr. Whitney pronounced a sloughing fibro-myoma.

For the next three days her condition remained about the same, the temperature rising to 103.5° F., and the pulse to 125: the vaginal discharge was still intermittent and very abundant, foul and purulent.

After these three days her condition improved decidedly: she became much less delirious: the temperature and pulse both fell; but there was a marked morning rise with an evening remission. The discharge had nearly ceased.

On the seventh day after the discharge of the tumor temperature and pulse were nearly normal. She was much more rational, but still made frequent attempts to get out of bed.

On the twelfth day after the discharge of the tumor, the thirty-sixth day after her delivery, she had practically recovered: her mind was clear, the vaginal discharge had ceased, the walls of the vagina were healthy, and the patient was sitting up.

Examination forty-three days after delivery, and seventeen days after the expulsion of the tumor: Uterus somewhat fixed; position, slight anteflexion; cervix, stellate laceration; depth, three and three fourths inches. Vaginal walls appeared healthy, with the exception of a few depressions and cicatrices resulting from the loss of tissue.

CASE II. In the service of Dr. W. E. Boardman. The patient, thirty-nine years of age, entered the Lying-in Hospital for her eighth confinement in the seventh and a half month of her pregnancy, having been advised outside to have labor induced because of a fibroid tumor of the uterus.

Examination under ether showed an interstitial tumor the size of a child's head in the anterior uterine wall.

On consultation it was decided to defer the operation one month in the interest of the child. On the following day, however, labor began, and in seventeen hours she was delivered of a still-born child weighing two and one quarter pounds: the presentation was half breech. The membranes and placenta came away without difficulty. She was given a vaginal douche every morning and evening, and a poultice over the abdomen.

The temperature rose the next evening to 103° F., and with the exception of one day remained above 100° F. throughout.

The patient was given supporting treatment, with small doses of ergot and iron frequently repeated, and enough morphia to make her comfortable.

By the fifth day the lochia had become very offensive, and there was much pain in the abdomen. The evening temperature was, however, but 101.4° F., and the pulse 90.

On the sixth day the tumor presented at the os, partly protruding.

On the eighth day the tumor was visible at the vulva; it was sloughing, and very offensive; small bits were readily detached.

The pulse throughout had remained below 100, but for the past three days the temperature had been gradually rising. The same treatment was continued.

On the tenth day, Dr. Boardman being absent from the city, the tumor was thoroughly removed by Dr. Richardson, and the uterine cavity washed out with dilute carbolic acid. That night the pulse ran up to 120, but the temperature fell somewhat.

Abundant food and stimulants were given, but on the following day peritonitis supervened, the patient collapsed, and at the end of six hours died. There was no autopsy. During the whole course of her sickness there had been no well-marked symptoms of septic absorption. She was nervous and worried about her condition from the first, slept and eat poorly, and seemed weak and exhausted.

DR. O. W. DOE also reported briefly a case of fibroid of the uterus complicating pregnancy to illustrate how little injurious effect this condition may exert at the time of labor in contrast with the serious results in the two cases reported by Dr. Richardson.

Mrs. P., thirty-nine years of age, first noticed, in February, 1878, an enlargement in the right iliac region about the size of a small orange. It was dull on percussion, and there was no sense of fluctuation. This continued to increase slowly in size until, in the latter part of 1881, the enlargement extended five inches above the level of the umbilicus on the right side.

The catamenia last appeared on August 23, 1881, having been always regular previously. Three months later she sought medical advice in London as to the cause of this sudden cessation, and was assured that it was only the beginning of the menopause. A month later, still feeling uncertain as to her condition, she returned to Boston, and consulted her family physician, Dr. J. M. Smith, of Barnstable, who found undeniable evidences of pregnancy, and referred her to Dr. W. H. Baker, of Boston, to whom I am indebted for the case.

She came under my care early in March. At that time the abdomen was very much distended and tense, the tumor apparently occupying that portion of the abdomen to the right and four inches above the level of the umbilicus. Respiration was very much impeded when lying down, so that in April she was obliged to rest in a semi-erect position, and suffered very much from sharp lancinating pains throughout the abdomen. These became so wearing upon her, and the dyspnœa so troublesome, that I decided to induce labor at the end of the eighth month.

The membranes were easily ruptured at 9.10 A. M. on April 23, 1882, the cervix being quite soft and yielding. Pains came on one hour later, and the child was born at 4.15 P. M., a healthy boy, weighing six pounds. One peculiarity of the labor was that after every vaginal examination the pains would recur frequently and be very strong in character, continuing so for nearly an hour, when they would become weak. There was no undue hæmorrhage, ergot having been given a short time before the expulsion of the child, and the convalescence was uninterrupted, the patient being able to travel sixty miles by rail at the end of four weeks.

After the placenta was removed the fibroid could be easily felt, and was about the size of the head of a ten-pound child; by vaginal examination it was found to extend to, but did not involve, the cervix.

On October 13th following the labor the probe passed eight and a half inches, and the tumor seemed to have diminished slightly in size.

DR. B. CUSHING, present by invitation, read a paper [1] giving the experience of the Ste. Mary's Infant Asylum

[1] See Boston Medical and Surgical Journal, vol. cx., No. 16.

and Lying-in Hospital. The inference which he seemed to draw from a study of the cases was, that however desirable it may be among the rich for the accoucheur to come to the bedside of his patient enveloped in a cloud of carbolic vapor, the poor do very well under pure air, if they are kept clean and do not have too much "doctoring."

DR. RICHARDSON stated that at the Boston Lying-in Hospital about half the admissions had been of single women, among whom the percentage of deaths was considerably in excess of the mortality in the other half.

Recent Literature.

Post-Nasal Catarrh and Diseases of the Nose Causing Deafness. By EDWARD WOAKES, M. D., Senior Aural Surgeon and Lecturer on Diseases of the Ear, London Hospital, Senior Surgeon Hospital for Diseases of the Throat, London. Illustrated with Wood Engravings. Philadelphia: P. Blakiston, Son & Co. 1884.

The same physiological principles which underlie a previous work by the author (Deafness, Giddiness, and Noises in the Head) are brought forward in this volume to explain the catarrhal lesions of the nose and naso-pharynx, of which ear disease is a secondary issue. The results of the author's studies have led him to certain conclusions in regard to the functions of the vaso-motor system, which are at variance with the opinions held by experimental physiologists at the present time. We search in vain through the book to discover the nature of these studies or for proof to substantiate the theories which the author advances. We shall, therefore, simply state what the hypotheses are upon which this work is founded without comment.

Disease of the nose and naso-pharynx, acute or chronic, of whatever kind, the author regards as a neurosis. The specific seat of this neurosis is to be found in the superior cervical ganglia of the sympathetic chain and their afferent and efferent branches. The anatomical elements of these ganglia are in organic communication with their afferent and efferent sympathetic nerves, which have a reflex relationship with one another. The ganglia are not only independent centres, but they are correlative organs as well, by means of which afferent tissue impressions from one direction are reflexly referred to a totally different tract where they take effect upon the blood-vessels, and, by enlarging or contracting their calibre, produce alterations of nutrition or of function in the areas affected by them.

The phenomena of an ordinary cold are explained by vessel dilatation in the parts of least resistance in response to an afferent impression (a chill) reflexly transferred from the respective ganglia of the sympathetic chain to the efferent area in the nose. The causes of the hypertrophic as well as the atrophic forms of catarrh, follicular disease of the pharynx, and pharyngitis sicca are all to be sought in some ganglionic neurosis and consequent vaso-motor deficiency. Why diseases pathologically distinct should have this common origin is accounted for by the assumption, which the author believes to be a fact, namely, "that every distinct histological structure has special corpuscles in the ganglion assigned for the regulation of the blood supplied to it, and with which set of corpuscles the nervi-vasorum of such special structures are severally connected." To show to what length the author's reflex-excito-vaso-motor-sympathetic theories lead him we quote the assertion, to be found on page 64, "that the mismanagement of a quinsy may compel the supervention of a peri- or endocarditis."

Turning from the theoretical to the practical portion of the book we find a good deal that is most useful. The importance of directing therapeutic measures to the nose and its adjacent structures in treating certain forms of ear disease is very properly strongly insisted upon. The external nasal meatus is considered the physiological end of the Eustachian tube. The tube is, therefore, as liable to obstruction from stenosis of the inferior nasal meatus as it is from a similar condition occurring in any part of its length. In the author's experience it is rare for the subjects of nasal polypi to complain of deafness, an exemption which is due to the fact that they seldom intrude into the inferior channel of the nose, which is the true auditory passage. The chapter on The Hygienic Management of the Catarrhally Predisposed is excellent. The description of the methods of examining the fauces, nose, and post-nasal space and the anatomical survey of these parts leave nothing to be desired. It is stated that Sir Andrew Clark was the first in England to draw attention to the post-nasal space and its contents. His contribution appeared in 1864, and in it the statement is made that the normal secretion of the pharyngeal tonsil is competent to convert starch into sugar.

The treatment of the different forms of nasal stenosis causing deafness is carefully considered. Besides mentioning all of the most useful modern operative procedures for removing the hypertrophied mucous membrane covering the turbinated bones, the author details his own method, which he employs in extreme cases. His instruments consist of a pair of thin forceps and a *nasal plough*. The part to be removed is first grasped by the forceps, then the plough, — a kind of gouge, — made to adapt itself to the forceps, is pushed along the nostril, and slices off whatever is to come away. The operator has never experienced any ill effects from the use of this instrument. We have had no experience with it, but we are aware of the hæmorrhage which sometimes follows the removal of this hypertrophied tissue even when done with the écraseur, and when considerable time — one to two hours — has been devoted to the operation. Although we cannot subscribe to all that this work contains we cordially acknowledge its originality. The whole of it is interesting, and a great deal of it of real value.

A Year Book of Therapeutics for 1883. Edited by ROYAL W. AMIDON, M. D. New York: G. P. Putnam's Sons. 250 pages.

This work is made up of short abstracts of articles on therapeutic topics which have appeared in many medical journals during the year 1883.

By far the larger number are taken from foreign journals and comparatively few from American publications. About fifty pages are given to a translation of a paper by Dr. Gaetano Rummo, entitled Experimental Studies on the Physiological Action of Iodoform.

Those who have not had an opportunity to look over the current literature on this subject may find the work of interest.

Clinical Lectures on Mental Diseases. By T. S. CLOUSTON, M. D. Edin., F. R. C. P. E. To which is added an Abstract of the Statutes of the United States and of the several States and Territories relating to the Custody of the Insane. By CHARLES F. FOLSOM, M. D. Philadelphia: Henry C. Lea's Son & Co. 1884.

In this book Dr. Clouston endeavors to treat the subject under consideration from a clinical and practical point of view. The book is, in fact, as will be seen by the title, a collection of lectures of a clinical nature. As is said in the preface, a good clinical lecture will appeal to the facts of disease as seen in actual cases. Direct appeals to the facts of nature make much more impression on students than any amount of elaborate descriptions. From these considerations Dr. Clouston was led to publish these lectures as a text-book for the use of his own students, and he hopes they may be useful to practitioners as well.

Two hundred and sixty cases of mental disease are described and embodied in these lectures, and there being only 550 pages in the book we thus get a case to every two pages. This is viewing the material somewhat as we would a pile of wood with reference to measuring it by the cord, but it gives in one word an idea of the wealth of clinical material made use of. Here are plenty of colors to paint with; can the writer make pictures out of them? Has he the ability, the patience, the discrimination, the accuracy to use them aright? The reader need not long hesitate on this point, for the attention and interest of the veriest tyro will be excited and caught, and held, we will venture to say, quite to the end of the volume.

The cases serve as a solid foundation of facts, which bring into clear relief the points which the writer wishes to emphasize, and we easily catch his meaning, and retain at least an impression of what he desires us to understand for some time afterward.

There are three ways of using cases in a medical book. The first is the general way, which is largely for effect, or for the purpose of showing extraordinary results. The second way is that of detail, in which trivial and unimportant data are mentioned at such length that the salient points are lost sight of, and the reader is wearied, bored, and uninstructed. The third way is the happy mean, in which there is enough of detail to show careful observation, but more particularly a short, definite, concise grouping together of the data which give an illustrative picture of the theory to be elucidated. The latter method Dr. Clouston is evidently master of. He details a case in such a satisfactory manner that it is nearly as good as having the patient in actual flesh and blood stand before us. Further than this he goes however, for his cases and text dovetail into each other so cleverly that both are necessary for a harmonious whole.

Dr. Clouston's book is not and cannot be regarded as a text-book, except in as far as it is a text-book for his students, and this is all that he intended. It is not a *system* of psychology. It is not a history of all that is known on the subject, comprised within a certain number of pages. And we regard it as fortunate that it is not, as in that case the amount of original research which now characterizes it might have been partially wanting. As it now stands it is an able and original contribution to the literature of an obscure and difficult subject founded on the experience and study of an unusually acute and practical observer.

Like other writers on mental diseases, Dr. Clouston gives us a system of classification. It is not German, it is not Swedish, but it is the old system of the English, modified and improved. Though a classification of symptoms and not real diseases, it is as good as can be hoped for at the present time. The states of morbid mental depression and painful feeling are classed under one head. Most cases of melancholia might be called mental pain, or Dr. Clouston would suggest *psychalgia*. This characteristic of pain in melancholia is important and should not be lost sight of, and therefore the name suggested is a good one. Carrying the same idea of nomenclature further, mania is called *psychampsia;* circular insanity, *psychorhythm;* monomania, *mono-psychosis*, etc.

In studying mental diseases it is necessary to bear in mind the general functions of the brain, and to make this clear Dr. Clouston places in a column on one side of several pages many of the normal conditions of the brain, and in a column on the other side the departures from, and modifications of, these conditions which tend to develop insanity. Such a means of comparison as this is very instructive, and graphic enough to adhere to the most logy of intellects.

One of the things that Dr. Clouston does not do, and for which he deserves our profound gratitude, is to give us a definition of insanity. Apparently the lower the ability of the writer on medical psychology, which Dr. Clouston aptly calls "Mind — as it concerns Doctors," the more determined is he to define with the greatest ambiguity that which may be regarded as undefinable. It strikes us as nearer the mark to deal gently, or not at all, with the incomprehensible, preferring rather the better part of shedding our feeble lights on such matters as we may be fairly supposed to understand.

The Abstract of the laws of the United States and the States and Territories, by Dr. C. F. Folsom, of Boston, has been carefully and well done, and is an important addition for the reader in this country to what may be considered as one of the most valuable series of original observations on mental diseases of recent years.

Elements of Modern Chemistry. By ADOLPHE WURTZ, Member of the Institute, etc. Second American Edition. Translated and Edited from the Fifth French Edition by WILLIAM H. GREENE, M. D., etc. With One Hundred and Thirty-two Illustrations. London and Philadelphia: J. B. Lippincott & Co. 1884.

The first American edition of this book was noticed at some length in the JOURNAL of February 12, 1880. We therefore consider it sufficient to state in this place that the book has been carefully revised and considerably enlarged. The most extensive additions are to be found in the organic portion, naturally, as the chief progress during the last few years has been made in this branch of the science. This book is one of the best of the smaller treatises on chemistry.

— The hypodermic use of pilocarpine is recommended for obstinate hiccough. A writer in the *St. Louis Courier of Medicine* describes a case in a man of seventy-three where the use of .03 gramme succeeded after all other attempts had failed. Other favorable results are also quoted.

Medical and Surgical Journal.

THURSDAY, JULY 10, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

AN ACT RELATING TO MEDICAL EXAMINERS AND CORONERS.

INFLUENCED, doubtless, by the fortunate experience of their Massachusetts neighbors, the legislators of Rhode Island have enacted a law bearing the descriptive title which is given above. Under its provisions the executive of the State has appointed twenty-four "able and discreet men, learned in the science of medicine, to be medical examiners." Of these twenty-four twenty are regular physicians in good standing, and we are assured that, on the whole, the selection of the new officers will be considered judicious, and will give very general satisfaction throughout the State.

The act contains a brief but very significant section repealing all statutes heretofore in force concerning coroners and their inquests, and provides that the present law shall go into full effect on the first day of the present month. The people of Rhode Island are now living, therefore, under the new system of inquests, and it is to be hoped for them and their public morals that the medical examiners will have very infrequent calls to duty.

In one important respect the Rhode Island law departs from the precedent offered in the Massachusetts statute. So far as the medical examiners and their duties are concerned the two statutes are very nearly identical, but in the matter of inquests Rhode Island, it appears, required what Massachusetts dispensed with, namely, the services of coroners. In Massachusetts when a medical examination results in the conclusion that a death was by "violence" the medical examiner reports the case to the justice of the district or municipal court in whose jurisdiction the dead body was found or the death occurred, and this judge holds the inquest and makes record of the material circumstances, issuing, if need be, a warrant for the arrest of suspected parties. But in Rhode Island the established judicial administration was deemed insufficient or unsuited to undertake this work, and "coroners" are to be elected triennially by the town councils for each town to do inquest duty. We see no advantage in this plan of independent inquest officers except the purely theoretical one that the interests of an accused person would, presumably, be a little safer under the decisions of a judge who had not previously heard the testimony at an inquest, and thus had not received a twist in his judgment. Moreover, the name "coroner" has an unfortunate odor sticking to it. If it were necessary to retain the office (bereft, of course, of the coroner's jury) we wish that the Rhode Island wisdom might have devised another title, such as "inquest justice;" even the incomprehensible Scotch name, "procurator fiscal," is preferable to coroner.

But waiving these objections, it gives us unalloyed satisfaction to record that the excellent Massachusetts plan of inquests is making progress, and that the lawmakers are recognizing the fact that a medico-legal investigation has two distinct elements, a medical element and a legal one. Certainly nothing could be more successful than the practical operation of this principle during the past seven years in Massachusetts; we confidently anticipate equally good results wherever the experiment is tried.

It is worthy of mention that the Rhode Island statute goes into effect upon the very day on which the second septennial period of the law begins in our own State. The commissions of those medical examiners who were appointed in June, 1877, and who continued in office during their full term of seven years, having expired, Governor Robinson has recently given an illustration of his conservatism and has paid a compliment to the good judgment of his predecessor, Governor Rice, by reappointing, with but a single exception, all the original medical examiners who were candidates for his favor. In three conspicuous cases the re-appointment was not desired, and these places have been filled very worthily by the choice of regular physicians of excellent reputation. It is greatly to the credit of the entire corps of medical examiners in Massachusetts, that upon a careful canvass of their record and after a clear notice that charges of misconduct, bad habits, and inefficiency would receive proper attention, his Excellency has seen no reason to make changes in the list, except in the one case which was controlled largely by geographical considerations.

We hopefully predict a continuance of the excellent success which has thus far attended the Massachusetts method of investigating violent deaths.

THE TRAVELERS' POCKET PHARMACY.

A CONTEMPORARY for whose opinions we have in general great respect discourses in a timely manner on the hygiene of summer travel. There is certainly room for a caution of the traveling public as to impurities of drinking-water, and as to the importance of prompt and regular attention to the calls of nature during the vicissitudes of journeying. Attempts to popularize a knowledge of hygiene are not to be lightly discouraged. But there is a limit, we believe, to the drugs which it is wise to place in the grip-sack of the average summer tourist. The list which our contemporary suggests as comprising the "small stock" that travelers will do well to provide and carry for preventing illness is as follows: —

"Seidlitz powders, cathartic pills, brandy, cholera-mixture, paregoric, aromatic spirits of ammonia, soda-mint, ginger, a few opium suppositories, quinine pills, and prepared mustard leaves."

Some of these drugs are tolerably active in their effects, and it is pleasant to know that the average traveler is so familiar with their therapeutic uses as to be able to employ them with precision and safety.

We have only to add that surgical casualties ought to be equally well provided for, and to suggest a similarly efficient armamentarium in that department. The prudent paterfamilias will do well to take in his valise a stomach pump, a few catheters, some splints, an amputating knife and saw, etc. Possibly it would be well to add a *trephine* and a *tracheotomy tube*.

We regret to say that it appears that the English are not always to be similarly trusted in carrying about and administering active drugs. Just after writing the foregoing paragraph we chanced upon the report of evidence before a coroner's jury in England by which it appeared that one Josiah Haynes, an auctioneer, having gone on a journey one day with his housekeeper, Mrs. Todd, gave her at the Victoria Park Station, as she was feeling ill, a "calomel" powder, "telling her to take it at bedtime, as it would do her good." It appeared, moreover, that about four years ago Mr. Haynes, wishing to kill a dog, had purchased from a friend, a druggist in Somersetshire, some strychnia, some of which he gave to the dog and killed it, whilst the remainder was put away in a box. A few days before the day in question, whilst turning over some papers, he accidentally came across it, and put it in his waistcoat pocket for safety. On reading an account of the case in the papers he felt in his pocket for the strychnia and found it gone, whilst the calomel powders were still there. Mrs. Todd had passed the "calomel" along to her father, wishing also to do him good. The parent unfortunately died of strychnia poisoning. The jury censured Haynes.

THE CHOLERA IN FRANCE.

SINCE our last issue the epidemic of cholera has been gradually increasing in Toulon and Marseilles, at least if it is to be measured by the records of daily deaths and of cases in the hospitals. The panic among the inhabitants cannot be taken as a measure of the extent of the disease or of the reality of the danger, for it has evidently been very much exaggerated. On the other hand, the intelligence emanating from government sources seems as little reliable for an exact index of the real condition prevailing.

Quantities of people are reported as having fled from Toulon and Marseilles, and trade in the former place seems to be completely at a stand-still. Later reports tend to confirm the statement that the disease was introduced at Toulon by the French transport Sarthe returning with troops from the East, and it is now said she had fourteen cases of cholera on board when in the Red Sea.

The weather in the South of France has been extremely hot of late, and the usual condition of the streets, the drains, and the houses in southern French towns is such as to offer, in connection with hot weather, all necessary facilities for the propagation of a disease like cholera. The unreasoning fear of the populace is another element aiding its spread.

Our general government and local authorities are, we are glad to see, taking suitable steps to guard against an introduction of the disease, and against extreme consequences should it find a lodgment on our shores, an event entirely within the bounds of possibility.

Whilst deprecating panics and senseless fears, it is equally our professional duty to discourage foolish writing about this disease being something else than true cholera, or that having reached its present proportions in populous centres, it is likely to retire propitiated by the limited number of victims hitherto secured. True courage and foresight are not made manifest by depreciating an enemy, least of all one which in times past has proved itself so formidable.

THE FISKE PRIZES.

Too little publicity, as it seems to us, is given to the details of the Fiske prizes, as by the limitations of the will of the late Dr. Fiske the trustees of the fund are permitted to advertise only in certain newspapers. For 1885 four prizes are offered, each of two hundred dollars. The following are the subjects proposed: —

I. Original Investigations in Household Hygiene.

II. The Present State of the Germ Theory of Disease.

III. Physiological and Pathological Effects of the Use of Tobacco.

IV. Migraine; its Nature and Treatment.

Every competitor for a premium is expected to forward to the secretary of the trustees, Charles W. Parsons, M. D., Providence, on or before the first day of May, 1885, free of all expense, a copy of his dissertation, with a motto written thereon, accompanying it with a sealed packet having the same motto on the outside, and his name and residence within.

The author of the successful dissertation must transfer to the trustees all his right, title, and interest in it for the benefit of the Fiske fund.

These prizes were established by the late Dr. Caleb Fiske, at one time president of the Rhode Island Medical Society, and the fund is in the hands of trustees who are members of that Society.

FREE BATHS IN WINTER.

DR. TAUZSKY, of New York, is endeavoring to inaugurate a movement for securing public bathing facilities for the poor of the great cities in the winter time. Free public baths for the summer months have become an established institution in many of the large cities, but warm baths for the "great unwashed" the year round are not as yet generally provided. We understand that the Society of Ethical Culture of New York has in its possession quite a large sum of money contributed for the elevation of the condition of the poor, some of which it is proposed to expend in this way. Compulsory cleanliness is harder to secure than

even compulsory vaccination, but it seems a pity that those of the poor who desire to be clean should not have facilities therefor. It is possible that emigrants whose condition warrants it might be compelled to bathe before landing, and if with the bath-house were associated a wash-house for the simultaneous purification of their clothing, it is possible that the measure might be of some value as a preventive of disease. We understand that in London arrangements of this sort are provided under the auspices of the several parishes. In this country obviously the proper channels for the establishment of such baths are the local boards of health.

MEDICAL NOTES.

NEW YORK.

— In the final estimate of city expenses for 1883 $25,000 was appropriated to enable the Commissioners of Charities and Correction to furnish additional accommodation for the pauper insane in their charge. A short time since the Commissioners selected 1067 acres of land on Long Island, between Farmingdale and Deer Park, for this purpose, and have now secured the approval of the Board of Estimate and Apportionment in making the purchase with the above appropriation.

— Dr. William M. Smith, Health Officer of the port, has issued orders to the effect that mails leaving French ports after the 28th ult. shall be detained for disinfection at quarantine, and that all French mails arriving from English or other ports, which leave such ports subsequent to the 30th ult. without having been disinfected at the port of departure or at the port where received from French ports, shall also be detained until disinfected. In addition, he requests that French mails via English ports should be isolated from other mails on shipboard, in order to facilitate the disinfection and release of such mails and prevent the necessity of disinfecting mails from other ports.

— The street-cleaning department seems to be fully alive to the necessity of keeping the streets as clean as possible, in view of the possible introduction of cholera into this country, and the Commissioner has intimated to the contractors that he would require of them more than ordinary attention this summer, particularly in those neighborhoods where some of the people are known to be careless in observing the ordinances and the rules and regulations of the Sanitary Code.

— Dr. Joel Foster, one of the oldest practicing physicians in the city, died on the 29th of June, after an illness of about six weeks. He was born at Barnard, Vt., March 10, 1802. He first studied medicine under Dr. Gallop at Woodstock, Vt., and afterwards attended lectures at the Jefferson Medical College of Philadelphia, from which he received the degree of M. D. He practiced for a number of years at Schoharie, N. Y., and in 1855 came to New York to live. When the President called for volunteer surgeons after the second battle of Bull Run, Dr. Foster secured thirty-seven physicians from the Academy of Medicine and started for the field, afterwards receiving honorable mention for his services. He was the oldest life member of the State Medical Society, and was one of the founders of the Academy of Medicine.

MEDICO-LEGAL NOTE.

— The *Weekly Drug News* remarks that Victor C. Vaughan, M. D., and James H. Dawson, Ph. C., have made experiments (abstract from Contributions from Chemical Laboratory, University of Michigan) with the view of determining whether or not arsenious oxide (common white arsenic) would diffuse through the body after it had been mixed with water and injected into the mouth or rectum after death, this having been the most important question which arose in a murder case tried in Michigan within the past year. They concluded, from experiments on dead bodies, that arsenic is widely diffused through the body when introduced after death, and that, therefore, in a case of suspected arsenical poisoning, if arsenic has been introduced into the body after death, the finding of the poison in the various organs is no proof that the arsenic was introduced during life and was the cause of death. Arsenical embalming fluids may, according to the above, be used as a means of covering up crime, and this fact should be borne in mind in cases of supposed poisoning by arsenic.

Miscellany.

TREATMENT OF ACUTE ABSCESS.

Professor Smith, of the University of New York, has recently published in the *Æsculapian* his treatment of acute abscess, for which he claims in the case reported a saving of at least a month to the patient. He advises a similar procedure in carbuncles and furuncles, in fact wherever there is necrosed tissue. The method is as follows: —

(1.) Wash well with soap and water and a flesh brush the skin at the seat of the operation, then douche with a solution of corrosive sublimate 1 to 500. (2.) Open the abscess with a knife treated with a solution of carbolic acid 1 to 30, the opening to be of a size to admit the nozzle of a Davidson syringe. (3.) Force out the contained pus by pressure, when it ceases to flow, introduce the nozzle of the syringe, well disinfected, the edges of the wound being held firmly around it, and distend the cavity to its fullest capacity with corrosive sublimate solution 1 to 5000. (4.) Force out the injected fluid by pressure. (5.) Repeat this injection as often as may be necessary until the water flows away quite undiscolored. (6.) Lay the cavity open to its full extent, keeping up irrigation with a corrosive sublimate solution 1 to 2000. (7.) Cut away all shreds of tissue, and scrape off gently any granulations that may be upon the living surface of the abscess by means of a curette, until a perfectly clean surface is everywhere apparent. (8.) Ligature any small vessels that may be bleeding with carbolized ligatures, thorough irrigation being kept up with the corrosive sublimate solution throughout. (9.) Close

the wound with an uninterrupted suture, except at the most dependent point, where a small opening must be left for drainage. (10.) Over the drainage opening place a disinfected sponge to absorb discharge. (11.) Sprinkle the external wound and adjacent skin with iodoform; cover the wound well with folds of gauze between which iodoform is well sprinkled; over the layers of gauze apply a dressing of borated cotton, and if in a limb, secure all by a light plaster-of-Paris bandage. In the case reported, that of a man with abscess in the thigh, the result of injury, and large enough to contain a pint, and to get at which an incision two inches deep had to be made, the suffering and fever before the operation was considerable. Temperature 103° F. The day after the operation the temperature fell to normal, and did not again rise to 100°; the pain ceased entirely, the appetite returned, and he enjoyed sound and undisturbed sleep. The patient stated that from his recovery from the anæsthetic he had felt entirely well. The dressing was removed on the eighth day. The wound was entirely closed, and though there was some thickening of the tissues involved in the injury there was no tenderness. He could walk without pain or inconvenience, and there was a rapid subsidence of the swelling of the part.

A MEMORIAL PROFESSORSHIP TO THE LATE DR. S. D. GROSS.

THE Alumni Association of Jefferson Medical College has inaugurated a movement to secure the endowment of a memorial professorship, to be designated the S. D. Gross Professorship of Pathological Anatomy. The profession at large, the personal friends of the late Professor Gross, and others who may be interested in such an object, are cordially invited to participate in this recognition of the services and extended reputation of the late Professor Gross.

Contributions may be sent to Dr. R. J. Dunglison, Treasurer, Lock Box 1274, Philadelphia P. O.

THE DIAGNOSIS OF SCIATICA.

A DIAGNOSTIC point in sciatica is given by De Beurmann[1] which we have never seen alluded to. The patient lying on his back with the muscles of the leg and back relaxed, the affected leg is raised while in complete extension and flexed upon the abdomen. This causes marked pain in the course of the sciatic, especially intense at the sciatic notch, and the movement is resisted. If, then, the limb be lowered, and while the leg is flexed on the thigh, the latter is again carried up on to the pelvis, no pain will be felt. This phenomenon depends on the fact, verified by De Beurmann in experiments on the cadaver, that great tension of the sciatic is exerted by flexion of the thigh when the leg is extended, but almost none when the leg is flexed.

In the diagnosis of sciatica from crural neuralgia, affection of the femur, or coxalgia, in all of which diseases the position of the limb and seat of the pain may be similar, this manœuvre is of value. If the nerve trunk is free of disease there will be no difference in the amount of pain caused by the extension or relaxation of the nerve by the different positions indicated. In other words, in affections other than sciatica, the movements given to the coxo-femoral articulation will be equally painful whether the leg is extended or flexed on the thigh.

THE MORTALITY OF MARRIED LIFE.

THE *Journal of the American Medical Association* cites some rather remarkable statements from an address delivered by Dr. William Pratt, of London, as follows: —

"According to statistics the married life is not only the purer, producing the minimum of evil-doers and criminals, but it is also by far the most healthy. Take the male sex, and it is seen that from twenty-five to thirty years of age one thousand married men furnish six deaths; one thousand bachelors furnish ten deaths; one thousand widowers furnish twenty-two deaths. The figures, however, become very unfavorable if the marriage be contracted before twenty. Out of eight thousand young men married before twenty their mortality has been found to be, before marriage, only seven per one thousand; after marriage, fifty per one thousand. With respect to the female sex we find a similar advantage of marriage over celibacy, but on the same condition. If young girls be turned into wives before twenty a like mortality befalls them which befalls the other sex. Everywhere young married people from eighteen to twenty years of age die as fast as old people from sixty to seventy years of age. The common sense and common law of Western Europe have with perfect justice marked twenty-one as the age of maturity. After that epoch, however, marriage should be contracted as soon as practicable. It is the healthiest and the happiest life; the best for the individual and for the community."

THE DRAWBACKS OF RANCH LIFE FOR THE PHTHISICAL.

IN a paper on Colorado for Invalids in the current number of the *Popular Science Monthly*, Dr. Samuel Augustus Fisk thus corrects what he considers a common mistake among Eastern consumptives going to Colorado for their health, as well as among the physicians sending them: —

It may be a good thing for the person affected with phthisis to go into ranching after he has been in the State long enough to know what he is about in doing so; but we enter a protest against the idea, which is somewhat prevalent in the East, that in order to recover his health the invalid should go on to a ranch and herd sheep. The reasons for making this protest are that such advice is frequently given, and, as we are led to judge, by physicians who have but the vaguest ideas of the nature of the course they are prescribing. The invalid, on coming to Colorado, needs to have life made as easy and pleasant for him as possible. As a rule, the sacrifices he has to make, in consequence of his sickness, render him for the time being peculiarly dependent upon sympathy. He should be so situated that he can have the benefit of pleasant society and diverting companionship. Now, ranch life is necessarily somewhat rough and usually monotonous, and when it

comes to herding sheep even a vigorous man, new at the business, finds it most irksome and fatiguing. We think it is a great mistake to increase the trials of an invalid by imposing upon him, in addition to a separation from his friends, an almost entire absence of companionship, a life that is rough in the extreme, and a dietary that is innutritious, uninviting, and monotonous. The average ranch house is a miserable shanty, out on the plains, away from neighbors, where the usual diet is bacon floating in grease; hot flapjacks, made fresh with water and baking-powder; molasses, and coffee without milk.

If it be possible for the invalid to go to some nice ranch, near a village, where he can have good, wholesome diet, pleasant associates, out-of-door occupation, and where his hours will necessarily be regular, then the conditions for recovery are excellent. Such ranches are to be found. But the average ranch, on the plains, is much inferior to the average farm-house in the East, and the surroundings and diet are such as, at first, to try very severely the strongest man.

The matter of diet is one to which, as it seems to the writer, sufficient attention is not usually paid by the invalid. He should be so situated that he can have an abundance of plain nutritious food, well cooked, and a variety sufficient to invite the palate. It stands to reason that if the waste in the system, produced by the disease, is not only to be made good, but it, in addition, as is desirable, the patient is to put on fat, he must take into his system material sufficient in quality and quantity wherewith to do it. Any place, be it on a ranch or at a boarding-house, where the table is uninviting and nauseous, is a bad one for the invalid, and one that he should leave as soon as possible. It is on this ground that we base a good deal of our objection to ranch life. As indicated, the food is usually poor in quality, insufficient in quantity, and indigestible. Contrary to what might be supposed, even on a cattle-ranch, milk is seldom to be had, and if the black coffee is to be drunk *au lait*, it is made so with condensed milk. The life, also, is monotonous and trying, and the distance from medical assistance, if needed, is so great as to be, in hæmorrhagic cases, of serious importance. The writer is convinced that ranch life, the so-called "ranch-cure for consumptives," especially those just out from the East, is a mistake; and he is certain that its good qualities, in giving occupation and an out-of-door life, are to be had without the bad ones by going to some one of the many towns on the eastern slopes of the Rocky Mountains.

REPORTED MORTALITY FOR THE WEEK ENDING JUNE 28, 1884.

Deaths reported 3109 (no reports from St. Louis and Buffalo): under five years of age, 1512; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 913, diarrhœal diseases 561, consumption 283, lung diseases 174, diphtheria and croup 82, measles 71, scarlet fever 54, typhoid fever 39, whooping-cough 27, malarial fevers 25, cerebro-spinal meningitis 21, erysipelas 18, small-pox eight, puerperal fever five, typhus fever two. From *scarlet fever*, New York 17, Philadelphia 11, Baltimore six, District of Columbia and Milwaukee three each, Brooklyn, Chicago, Boston, and New Orleans two each, Cincinnati, Pittsburg, Providence, Waltham, Weymouth, and Salisbury one each. From *typhoid fever*, Philadelphia eight, New York and Chicago five each, Boston, Baltimore, and New Orleans three each, Pittsburg, Providence, and Nashville two each, Cincinnati, Milwaukee, New Haven, Charleston, Worcester, and Lynn one each. From *whooping-cough*, New York and Brooklyn four each, Boston, Cincinnati, and New Orleans three each, Chicago, Baltimore, Pittsburg, and Milwaukee two each, District of Columbia and Somerville one each. From *malarial fevers*, New York eight, Brooklyn and New Orleans four each, Chicago and Baltimore three each, Philadelphia two, District of Columbia one. From *cerebro-spinal meningitis*, New York five, Philadelphia and Chicago three each, Milwaukee, Nashville, and Worcester two each, Boston, Cambridge, Brockton, and Peabody one each. From *erysipelas*, New York seven, Chicago, Boston, and Baltimore two each, Philadelphia, Brooklyn, Cincinnati, Providence, and Worcester one each. From *small-pox*, New Orleans four, Philadelphia two, Baltimore and Nashville one each. From *puerperal fever*, New York, Chicago, Boston, Milwaukee, and Charleston one each. From *typhus fever*, New York two.

One case of small-pox was reported in Cincinnati; scarlet fever 38, diphtheria 23, and typhoid fever five in Boston; scarlet fever 34 and diphtheria six in Milwaukee.

In 105 cities and towns in Massachusetts, with an estimated population of 1,420,465 (estimated population of the State 1,955,104), the total death-rate for the week was 15.41 against 15.00 and 14.40 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending June 14th, the death-rate was 19.8. Deaths reported 3326: acute diseases of the respiratory organs (London) 246, whooping-cough 121, measles 163, scarlet fever 66, diarrhœa 63, fever 33, small-pox (London 27, Liverpool five, Sheffield one) 33, diphtheria 29. The death-rates ranged from 13.4 in Brighton to 28 in Wolverhampton; Bradford 14.7; Nottingham 17; Leicester 17.7; London 18.8; Birmingham 18.8; Sheffield 18.9; Leeds 22.8; Manchester 23.9; Liverpool 26.9. In Edinburgh 21.4; Glasgow 26.7; Dublin 21.7.

For the week ending June 14th, in the Swiss towns, there were 38 deaths from consumption, diarrhœal diseases 21, lung diseases 20, typhoid fever 21, diphtheria and croup six, whooping-cough three, measles two, erysipelas two, small-pox one, scarlet fever one. The death-rates were, at Geneva 21.4; Zurich 15.7; Berne 37.8.

The meteorological record for the week ending June 28th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JUNE 28, 1884, TO JULY 3, 1884.

HARTSUFF, ALBERT, major and surgeon (Fort Riley, Kansas). Granted leave of absence for one month, with permission to apply for one month's extension, to take effect when his services can be spared. Paragraph 6, S. O. 130, headquarters Department of Missouri, June 25, 1884.

MIDDLETON, J. V. D., major and surgeon. Ordered to relieve Surgeon B. E. Fryer from duty as post surgeon, Fort Leavenworth, Kansas, on or before July 1st. Paragraph 5, S. O. 133, headquarters Department of Missouri, June 28, 1884.

DICKSON, JNO. M., captain and assistant surgeon. Assigned to duty as post surgeon, Alcatraz Island, California. Paragraph 3, S. O. 71, headquarters Department of California, June 19, 1884.

GIRARD, A. C., captain and assistant surgeon. Granted leave of absence for six months, with permission to go beyond sea. Paragraph 11, S. O. 148, A. G. O., June 26, 1884.

GIRARD, J. B., captain and assistant surgeon. Ordered to relieve Surgeon W. E. Waters from duty as post surgeon, Plattsburg Barracks, Plattsburg, N. Y. Surgeon Waters, upon being relieved, directed to return to his proper station (Madison Barracks, N. Y.). Paragraph 3, S. O. 131, headquarters Department of the East, June 30, 1884.

BENHAM, R. B., first lieutenant and assistant surgeon. From Department of Dakota to Department of Texas.

GORGAS, WILLIAM C., first lieutenant and assistant surgeon. From Department of Texas to Department of Dakota. Paragraph 8, S. O. 150, A. G. O., June 28, 1884.

WALES, PHILIP G., first lieutenant and assistant surgeon. From Old Fort Colville, Washington Territory, to Fort Cœur d'Alene, Idaho. Paragraph 3, S. O. 89, headquarters Department of Columbia, June 23, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JULY 5, 1884.

WELLS, H. M., surgeon, detached from Naval Hospital, Brooklyn, ordered to U. S. S. Lancaster.

DR. J. S. SAYRE, DR. F. J. B. CORDEIRO, appointed assistant surgeons. Commissions dated 27 June, 1884.

BOOKS AND PAMPHLETS RECEIVED. — Auscultation, Percussion, and Urinalysis. An Epitome. Edited by C. Henri Leonard, A. M., M. D. Fully Illustrated. Detroit, Mich. 1883.

The Sixtieth Annual Report of the Officers of the Retreat for the Insane at Hartford, Conn. April, 1884.

Address.

THE PHYSICIAN A POPULAR EDUCATOR.

THE ANNUAL DISCOURSE BEFORE THE MASSACHUSETTS MEDICAL SOCIETY, JUNE 11, 1884.

BY JOHN CROWELL, M. D., OF HAVERHILL.

Mr. President and Fellows of the Massachusetts Medical Society, — We live in an age remarkable for successful industry in every department of human skill and enterprise. Each day adds to the stock of man's inventive faculty in the curious mechanisms for the quicker and easier accomplishment of labor, and the splendid results are seen in every town and hamlet in the land. Material prosperity, as one of the elements of our civilization, is also shown in the colossal fortunes amassed in our great cities, and in the monuments of skillful labor that adorn our streets, and stretch from sea to sea in a net-work of iron bands.

We hear the almost boastful cry of the successful men of vast financial achievements, and the lips of praise do swift homage to those giants who control great enterprises and hold the stock market in the palm of the hand.

Amid the devotion paid to the energy and the force that move this mighty machinery of business, amid all our admiration for the wealth that builds cities, founds schools, endows hospitals, and contributes to the thousand charities that appeal to our humanity, let us inquire into another phase of a nation's greatness, — the intellectual elements that shape the thought and give direction to those movements without which material prosperity would work its own decay.

The present age is quite as remarkable for scientific investigation and philosophic research, for acute analysis and profound questioning, as for any material success and splendor. Against the achievements of the Rothschilds and the Vanderbilts we place the Pasteurs, the Darwins, the Spencers, and the Bains. Philosophy, science, and philology are also the products of our time, and stand side by side, and quietly but firmly hold their own with the more pretentious forms of success that mark the industry of man.

The exalted position of the medical profession to-day is largely due to the patient investigations of the scientist in the laboratory and with the microscope. While the great world has pursued its noisy way the scholar has been busy in the recluse of his inner sanctuary[1] solving those problems, and unfolding those subtle theories that challenge our respect and admiration. Recent contributions to medical science form an epoch in our history. Who can estimate the value of that treasure-house, the chemical laboratory? What wonders in pathological analysis are daily unfolded by the microscope! How, by the invention and use of the most delicate instruments, can we detect the faintest indication of incipient disease! How, by minute dissection and a thorough understanding of the adaptation and relations of bone and muscle, fibre and tissue, some of the recent triumphs in operative surgery have been obtained! How broad and generous have become the modes of thought that give shape to our literature, and place our profession among the foremost of the learned systems of the world!

1 "The laboratory is the forecourt of the Temple of Philosophy; and whoso has not offered sacrifices and undergone purification there has little chance of admission into the sanctuary." — Huxley, Life of Hume.

This is seen in the sharpness with which the investigations, and theories, and hypotheses of scientists are challenged by their peers. No sooner does Robert Koch startle and delight the medical world by his Ætiology of Tuberculosis,[2] showing the result of a long series of microscopical experiments, than a score of enthusiastic investigators review his experiments, and out of Stricher's laboratory comes Spina[3] with a series of investigations calculated to completely overthrow Koch's theory which had made so promising a foot-hold, denying by the same line of experiments his most brilliant conclusions.[4]

To the physician whose experience stretches over a quarter of a century the condition of medical science to-day is full of sharp contrasts. He compares the abundant facilities for preliminary study with his own scanty resources in the days of his pupilage. He visits yonder building[5] with all its generous spaces and magnificent appliances; he examines the curriculum with its wide range of general and technical study; he sees the system of teaching and the methods of illustration conducted from a broader basis of scientific research and investigation; he looks with admiration upon the enthusiasm of the student, as, with an honest emulation, he works in the laboratory or in the dissecting room; and he mentally exclaims, "Would that I were young again, to revel in all this wealth of advantage and opportunity!"

But this evolution in medical teaching is but the outgrowth of humble beginnings. The foundations laid by the fathers were well laid, and, year by year, we have witness of their wisdom, and zeal, and patience in preparing the way for these larger results.

How redolent of honest praise are the names of Warren and Jackson and Bigelow. What a debt of gratitude we owe to those great lights in medical science that have just disappeared from our horizon. How universal is the homage paid to the genius of Sims, and Parker, and Gross, whose wise and profound teachings, combined with the labors of our eminent living teachers, have shaped the methods, and guided the research of modern thought and investigation, —

> "With truth's directness, meeting each occasion,
> Straight as a line of light."

The example of the University in establishing a sounder system of medical education has been productive of wholesome results. And, inspired and impelled by the example, the other great medical schools of the land are revising their courses of study, and broadening and deepening their methods of instruction. So that the ambitious student, desirous of obtaining a thorough preparation for the great duties of our profession, finds the doors of science wide open to invite and to receive him, that she may unfold her mystic stores.

As the preparations for the work of the profession are so ample, as the avenues to success are so full of dignity and honor, how steadfast and noble should be the allegiance to the hand that has led us on. For, as Lord Bacon expresses it: "I hold every man a debtor to his profession; from the which as men of course do

2 Die Etiologie das Tuberculose, Berliner klin., 1882.

3 Studien ueber Tuberculose, Wien, 1883.

4 And what is this contest but a repetition of the profound conception of Aristotle, that "Science begins when from a great number of experiences one general conception is formed which will embrace all similar cases."

5 New Building of the Harvard Medical School, Boylston Street, Boston, dedicated October 17, 1883.

seek to receive countenance and profit, so ought they of duty to endeavor themselves by way of amends to be a help and ornament thereto." [1]

The physician, by the special discipline for his work, and by the delicate relations he sustains to his patients, enlists confidence, and his opinions carry the weight of authority. He stands at those gateways of anguish that open and close upon mortal life. His fingers are upon those delicate keys whose slightest touch vibrates through a thousand strings. His well-attuned ear detects the faintest discord in the vital harmonies, and the varying phases of morbid action cannot escape the searchings of his aided vision.

But there are relations of a more general character that demand our attention. The great public is ignorant upon matters of vital interest, and it may not be unprofitable to use the indulgence of this hour and consider the attitude of the

PHYSICIAN AS A POPULAR EDUCATOR.

What, then, are some of the topics that claim attention in our *general* relations to the community? Foremost stands the prolific question of Sanitary Science.

The literature of hygiene has been scattered broadcast ove. the land during the last decade. Science has been busy in unfolding to the public the more common sources of disease as found in house-drainage and in the ordinary methods of disposing of sewage. When the modern system of household appliances was first introduced into our dwellings we were so fascinated with the ingenious contrivances that they found a ready place in every part of our houses. Bedrooms, passageways, and halls were adorned with the glitter of marble basin and plated faucet, while convenient bathrooms opened directly into the sleeping apartments of guests, without much reference to the character of the plumbing or the construction of sewers. As a result, fine residences became the receptacles of filth distributed in an ingenious net-work of piping, as if contrived especially for the introduction of disease from cellar to attic.

This condition has been largely modified by the intelligent oversight of Boards of Health, and under the guidance of our State Board rapid strides are being made towards the remedying of many popular delusions. Still, much ignorance prevails concerning the simplest rules of health as respects domestic arrangements, and the physician by his familiarity with the location and the construction of houses can, by timely interference, reform many grave errors, and prevent their repetition in newly-constructed homes.

The ambitious and successful business man, anxious to build a fine house, is apt to leave the plan of its construction entirely to the architect, who too often concentrates his thought upon the æsthetic aspects of the structure, so appealing to the eye and so gratifying to the taste. The essential provision for plumbing and drainage is dealt with as of secondary importance, and the house of our friend and patient which we are expected to praise and admire is full of the results of bungling plumbing, and leaky pipes and a damp cellar unconsciously defile and dim the pretentious beauty of drawing-room and hall.

Says a recent writer of high authority in sanitary science. "The majority of even the best houses are now very badly drained, and are subject to the production of sewer-gas at many points between the outer wall of the house and the fixtures within it. Occupants are generally careless or ignorant of this fact, and the verdict of 'my plumber' is still considered by the average house owner a sufficient certificate of good sanitary condition. Large traps clogged with accumulations of putrefying kitchen waste, soapy compounds, fæcal matter, etc., are still the rule rather than the exception." [2]

(*To be concluded.*)

A CASE OF MYXŒDEMA, WITH AUTOPSY.[3]

BY E. G. WEST, M. D.

IN reporting this case of myxœdema, in which I was so fortunate as to secure an autopsy, — the only one, I believe, which has taken place in this country, — I shall try to mention fully *all* the symptoms noted by me and their development, even at the risk of being too diffuse, in order that in the subsequent study of this strange disease this report may be as full as possible, and for fear that some of the symptoms which may now appear of no value may prove to be of the greatest importance.

My patient, Mrs. P., was of American parentage and fair circumstances. Her father died at the age of fifty-eight of insanity, brought on by a blow upon the head. Her mother, now sixty years old, has a highly nervous temperament, and has suffered from gastralgia and other neuroses since her girlhood.

Mrs. P. was born and brought up in Roxbury, now a part of Boston, and during childhood contracted and passed through the measles, whooping-cough, and chicken-pox, but never had an attack of scarlet fever. At the age of fourteen she began to menstruate, and at seventeen had a mild attack of typhoid fever, which left no sequelæ. At about the age of sixteen, during the winter, when the snow was deep, she was suddenly awakened from a deep sleep, in the middle of the night, by a steam fire engine being stuck in the snow immediately in front of the house. She thought the house was on fire, which produced such a shock that for days, even weeks, she would often start out of sleep greatly frightened and crying, but this soon passed off. I note this fact inasmuch as almost all observers have noticed a similar mental shock, though very much worse than this. She has always enjoyed a peculiarly happy home and many advantages. She was very pretty and bright, and a good pianist, indeed, she played the piano long after her marriage for the Sunday-school of Rev. Dr. Patterson's church. She was slightly built, and never a strong girl, though generally considered as enjoying good health. She was married at the age of twenty. A few weeks after this she caught her hoop-skirt and fell down the front steps and hurt herself badly, but soon recovered. After this she fell down a whole flight of stairs. Soon after this, also after a severe effort, she suffered pain in the epigastrium, probably of the same nature as her mother's gastralgia, and for a long time this would return after almost every immoderate exertion.

At the age of twenty-two, or two years after her

[3] Read before the Section for Clinical Medicine, Pathology, and Hygiene of the Suffolk District Medical Society, May 14, 1884.

marriage, she gave birth to her first son. Nothing abnormal occurred during either gestation or parturition, and she was about the house in four weeks, but seven weeks after the birth both her legs swelled somewhat, and gave her considerable trouble, and although a diagnosis of phlegmasia dolens or milk leg was made by the practitioner in attendance still she was not confined to her bed, and there were no inflammatory symptoms, and she suffered an aching sensation rather than a pain. I shall anticipate by saying that no evidence of inflammation of the saphenous vein was found at the autopsy, and that the true beginning of the disease was here, thirteen years before her death, though the family set the beginning four years later. She lost a good part of her milk at this time, and was obliged to use the bottle as well as her breasts. After a few weeks she improved in health, and gained flesh, but was never as strong as before. About this time also she had a second attack of the measles, which left no observable sequelæ.

Two years after this, when she was twenty-four years old, she gave birth to her second son, with no abnormal symptoms before, during, or after confinement, except a great clumsiness, which came on during this pregnancy, and grew gradually worse through her whole life, and was the only symptom of incoördination present.

Two years after this, or when she was twenty-six years old, she gave birth to a daughter, and while carrying this child she suffered from cold and chilly sensations, and the legs and the veins in them swelled somewhat and gave her a great deal of trouble. She passed through parturition, and got up without abnormal symptoms of any sort. It is from this time that the family dates the origin of her disease, though I think it commenced soon after the first child. After nursing the babe for three months a feeling of pressure and heaviness was experienced in her arms, and later in her legs. They felt, as she expressed herself, as if her baby had rested upon them all night; this gradually grew worse, and her arms felt as if they would give out while practicing the piano, and soon she was obliged to give up playing at church. She used to joke about having "milk legs in her arms" at this time. While nursing the baby she also had severe pains in the abdomen, and thought she was going to have gastralgia through her life like her mother, but this passed off afterwards. She weaned her babe after nine months' nursing. At this time she described her legs as looking like "pig pork." Her appetite was good, and she slept and ate well, indeed, she could sleep at any time. Her back was very lame.

Mrs. P. was now treated with electricity, and improved somewhat, but during the next two years she became very fleshy, and grew gradually weaker and more clumsy, and her tongue thick and stiff. At this time the children (who are now quite strong and bright except the girl, who is rather delicate) had whooping-cough, and she got thoroughly tired out and was worse. She was not confined to bed, but after an attack of faintness when once alone, she gave up her cares and housekeeping and lived with her mother. She described herself as having no limberness anywhere, and as feeling like a stiff old lady even though she was only twenty-eight years old. She never went out alone, and when taking an airing she felt as if she could never get back, and dreaded crossing the street, and felt like catching hold of the fence and walking by it. She dreaded crowded places, and was liable to suddenly become dizzy and faint. She was always chilly, and wore a shawl even in hottest weather, her hands and feet were especially cold, and her head hot. She could not apply herself to anything.

At about this time Dr. Cheever removed several polypi from her nose, but with no undue hæmorrhage.

These symptoms continued with greater or less severity until December, 1881, when she first came under my observation and care. She had not then menstruated for over eleven weeks, and was fearful that she was again pregnant, which fortunately proved not correct. She had never miscarried in her life. Her condition then was like one suffering from chronic Bright's disease, for which I must certainly admit that I took it, and it was not until after constant observation, taking notes, and study of her symptoms, that I was shaken in my diagnosis and had to abandon it.

Her temperament was the most calm and deliberate, unruffled and unirritable I ever saw, even with her children who were apt to be rogues. Her facial appearance was very noticeable, all expression seemed to be ironed out, so to speak. The hair had fallen out so that it was very thin, and from the line of demarkation of the forehead backward there was a peculiar yellowness of the scalp as if stained by bile pigments, but this was the only part of the body so stained, and the pigment still remained even after repeated washings in borax, sapo viridis, etc, etc. Her forehead was clear, but the eyelids were very characteristic; they would puff out and become baggy and translucent, sometimes to such an extent that she could hardly open her eyes, and it was never wholly absent. The contents could be driven out by pinching, like the ordinary œdema. She was troubled about seeing, but sight was better in the right eye than in the left, and when I examined the eyes with the ophthalmoscope there seemed to be a sclerosis of the vessels of the retina about the optic nerve, and the whitish patch was larger in the left than in the right eye.

Her cheeks were swollen, nose was broad and thick, and lips large and protruding. The swelling here was not like that of the eyelids, which was puffy and translucent, nor the peculiar appearance of Bright's disease, but a thickness and heaviness. The skin of her whole body was rough, more especially of the hands and feet, and more noticeable in cold weather than in warm, and had the appearance of a general chronic eczema. Her cheeks had a most remarkable dusky reddish-purple hue which never faded away, but always remained and gave a semi-appearance of health to the casual observer. The mucous membrane of the lips and mouth had a deeper color even to a violet, except the tongue, which was pale in comparison.

Her tongue was entirely too large for her mouth, and indented with her teeth, and although her throat was large and broad still I could only with difficulty press down the tongue so as to get a view of the pharynx, which was rather pale than otherwise. The flesh of the tongue also had a harder feel than is usual.

She had lost some of the acuteness in hearing, and to a great extent that of taste and smell, especially when she was suffering from a cold, when everything tasted alike, and she had no choice in foods.

And here it would be well to mention her great liability to attacks of coryza and mild bronchitis, of catching cold, which she was continually doing in spite of precautions, and particularly in cold weather, when

she was almost never free from it. Another peculiarity of the throat was that she had great difficulty in swallowing solids, being obliged to make several attempts before she succeeded.

Her voice and speech were very characteristic. The former was roughened, lowered, and nasal, and the latter was slow, deliberate, and rather indistinct. She dreaded talking with strangers. Her intellect was bright and clear; she was often witty, and understood her condition. There was nothing observable in the neck from external examination for or against the presence or absence of the thyroid gland. She slept soundly, though she almost always dreamed and snored very loudly. She would drop asleep in the daytime, particularly in the winter, even while talking; once she went to sleep while eating her breakfast, at another time while making her bed, which was about the only work she did.

She felt best in the hottest days of the summer, when she would perspire quite freely; at no other time did she perspire at all. (This was a valuable suggestion in my treatment of the case.)

There were no symptoms pointing towards the heart and lungs, and upon physical examination I found nothing. The heart sounds were clear and distinct though rather weak, and the size of the organ was normal. Her stomach was always in capital condition, her food never hurt her and seemed to be well assimilated. Her bowels were regular; as a rule, she had two movements a day, rarely she was constipated for a few days, and two or three times she suffered from a slight diarrhœa, while under my care. Her abdomen was enlarged, and she felt a dull heaviness, and imagined she might have a tumor of some sort. Her back gave her a great deal of trouble, she could not get upstairs with anything heavy in her hands, and complained of giving out altogether. She had some leucorrhœa, which yielded to mild treatment.

Upon examination of the abdomen the walls were so flaccid I could feel the spine. The liver was normal in size, as was also the spleen, but there was evidence of some fluid in the flanks which changed with the position of the patient. This afterwards disappeared and the walls grew quite fat.

Both legs were large and white and she used them clumsily. They were cold in all weather, and she could not get warm till night. There was a small amount of pitting on pressure over the tibiæ, but nowhere else. Her feet were enlarged, and horny in feeling, like her hands. She could not balance herself upon one leg at all; when trying this she experienced a tickling and numb sensation in her knees, which was especially marked when she knelt down. She could distinguish heat from cold when applied, and the tactile points on the calf were about two inches apart as tried by the compass. During the beginning of the disease, as I have noted before, she would often joke about having "milk legs" in her arms. Her hands and fingers were swollen, but by no means club-shaped or like a fin as they have been described, though they had a tendency that way. She could write a beautiful hand even to the last. Her pulse stood at about seventy-five beats per minute. I never had occasion to take her temperature, but I have no doubt from the general coldness of the skin that it would have stood below normal, as most observers have found it to be.

She remained under my care from December, 1881, to the following November. As I have noted before, she consulted me about her catamenia, which had been absent eleven weeks, but the uterus was not enlarged, and under iron and tonics, good feeding, and diuretics she came around at fifteen weeks, and was fairly regular for more than a year after, when she was again troubled in this way.

I kept a special watch over her *urine*, making it one of the chief guides to my treatment.

The first examination which I made, on November 19, 1881, gave the specific gravity 1012, and no albumen nor casts. On December 7th, when the quantity was about thirty ounces, the specific gravity was 1015, and there was a slight trace of albumen and *no sugar*, and only a very few hyaline and granular casts. This was the only time I ever found any casts, though I have spent a great deal of time hunting for them, in the thirty odd analyses that I made. Her urine was measured each day for the first week she was under my care without treatment: the largest quantity was thirty-eight ounces and the lowest twenty-three ounces, with an average of twenty-nine ounces, and specific gravity 1010.

It will be seen from this that the excretion of solids, especially urea, by the kidneys was about one fourth of what it should have been in a healthy person. The kidneys reacted very quickly under diuretics, and the quantity jumped to seventy-eight ounces on the second day, with specific gravity 1006, and slight trace of albumen. The record after this shows an average daily amount of about fifty-two ounces and specific gravity 1010. Out of thirty-three analyses, in two only was there a trace of albumen.

	Quantity in Ounces.			Specific Gravity.			No. of Ex.	Albumen.
	Highest.	Lowest.	Average.	Highest.	Lowest.	Average.		
January, 1882	83 oz.	40 oz.	66 oz.	1013	1008	1010	7	Once only slight trace.
February, 1882	77	40	56	1012	1007	1010	6	Once only slight trace.
March, 1882	79	30	52	1013	1008	1010½	6	None.

October, 1882	76	34	50	-	-	-	-	-
Jan. before treat. began.	34	23	29	-	-	1010	1	None.
May 7, 1883	-	-	50	-	-	1012	1	None.

Mrs. P. improved considerably under treatment. She slept better, the eyelids improved, and water left the abdomen; her catamenia came about regularly, and she seemed to be gaining healthy flesh.

Dr. Minot was called in consultation in September, 1882, and thought that, upon the whole, it was a case of Bright's disease.

Dr. Edes saw her with me in October, about four weeks afterwards, and thought that it was a case of myxœdema. It was chilly weather by this time, and she was feeling a little worse. Her friends were very desirous that she should try that far-famed and much-advertised Warner's Kidney Cure, an example of one of the disgraces of our civilization. After a single analysis of her urine, a part of which I analyzed myself, the only abnormal thing about it being a low specific gravity, without seeing the patient Warner pronounced it the beginning of Bright's disease, and ordered his Cure. During the next six months she took forty-two bottles, with no effect whatever, except what might be practicably attributed to the diuretics and hot-air baths, which she did not give up. There was certainly no change for her good, and she was considerably worse when she returned to me.

I met the patient frequently during this period, and was called in to see the children several times, but it was not until the 17th of September that I again saw her professionally. Then she complained of dizziness, and the face and whole system seemed to have swollen more than ever, and the dusky reddish-purple of the cheeks had deepened.

She had much difficulty in swallowing, and the tongue was more swollen. She found considerable difficulty in using her jaws on account of stiffness, and finally just before her death she about gave up chewing, and I was obliged to recommend soups almost entirely for her nourishment. She was also troubled with dyspnœa on exertion, and would get very tired upon doing the smallest things. The dyspnœa was more observable when she was asleep and had no control over herself; then she had the peculiar "Cheyne-Stokes" respiration. She slept a great deal in the day-time, and the interval between the shorter and the long deep breath was often so great as to be alarming, and her mother would frequently shake her to awaken her. The face was more stupid, though her intellect was as as bright as ever. Her temperament was unchanged; the same calm and quietude. She spoke of a stuffy sensation in the nose, and upon examination I found and removed with a snare a mucous polypus, one piece of which was as large as the last phalanx of the thumb, but it did not seem to improve her speech much. There was but little hæmorrhage, and even that spontaneously stopped.

This was in the last of November, and the dyspnœa and difficulty in eating gradually increased until the 9th of December, when she died quite suddenly. During the last day or two she perspired quite freely, even though it was quite cold. She knew without my telling her that the end was near at hand, and her calmness was supreme. Her death cannot but be considered an accident in the disease, and due to the local cause, for her general condition was such that she could have lived at least many months longer, and possibly many years. Her bad dreaming had returned, and sometimes she seemed to dream when half awake and half asleep. The night before her death her husband had to light the gas before he could persuade her that she was awake. The evening of her death she appeared to enjoy herself very well, but that night she passed away quietly in her sleep, not even disturbing her husband, who was lying beside her. Her mother, who slept in the next room, became aware of her condition when she ceased snoring, which awakened her.

Unfortunately, I made no chemical or microscopical examination of the blood.

DIAGNOSIS.

As to the *diagnosis*, it would lie between chronic nephritis, pernicious anæmia, and myxœdema.

The examination of the urine would exclude *chronic nephritis;* besides, the general œdema was not of that kind. It was hard, and would not pit with pressure, except at the beginning of the disease, when I think it was due to anæmia, which the iron and diuretics soon remedied. Besides, after nine years' standing one would expect to find hypertrophy of the heart, which was not present.

As to *pernicious anæmia*, it is unfortunate that there was no examination of the blood, which would have excluded this; there was no appearance of that intense anæmia in the facies; on the contrary, a flush in the cheeks; the long duration would be against it. There were no hæmorrhages; indeed, wounds healed very well. The œdema was not that of a general anasarca. There were no paroxysms of fever, but, on the contrary, rather a constant lower temperature than normal.

We have left that strange disease, *myxœdema*, all of the characteristic signs of which were present. Indeed, the description of Dr. Drewit's case[1] would correspond to my own almost exactly, as did also that of Dr. James Allan[2] and Dr. Edes's first case: They were all women; the duration of the disease; the mental strain, shock, or hardship; the rapid growth from slight to large, fleshy women; slow, languid motion; fear in going about alone; the even disposition, never irritable; chilliness even in summer; absence of perspiration; partial loss of taste, sight, and hearing; the round, fat face; the swollen, translucent, wax-like skin; the broad nose, thick, coarse, purple lips; the dusky, reddish-purple cheeks; the eyelids pendulous and transparent; the tongue pale, swollen, too large for the mouth; the abdomen enlarged, as if with fat, nowhere pitting on pressure; the universal swelling; the skin of extremities rough, hard, and scaly; no disease of the lungs, heart, liver, or kidneys; temperature lower than normal, 95° F.; urine of low specific gravity, and diminished excretion of solids; no albumen nor sugar. In addition to these, my patient, among other things, showed great liability to catching cold, difficulty in swallowing, stiffness of the jaws, sleepiness, and the "Cheyne-Stokes" respiration.

ÆTIOLOGY.

The usual cause has been assigned to mental shock or great hardship, which has worn on the nervous system. This certainly was not the case in my patient.

Possibly the shock she received at sixteen, and the heavy fall between twenty and twenty-one, may have favored it, but it is highly improbable. She had an ex-

[1] As reported in British Medical Journal, December 1, 1883.
[2] British Medical Journal, February 9, 1884.

ceedingly happy home, and everything possible for her comfort.

It seems more probable that the insanity which developed in the father and the neuroses in the mother were transmitted in some unaccountable way, and became this strange disease in the child.

TREATMENT.

When I was convinced it was myxœdema instead of chronic Bright's disease, I could find no suggestions, and therefore adopted expectant treatment. I found her urine of low specific gravity and half its usual quantity and therefore gave diuretics, which brought the urine up to normal amount and increased the elimination of solids, though even then it reached only one half the normal amount. I tried bromine, digitalis, etc., but obtained the best results from simple cream-of-tartar water, one pint in twenty-four hours, which seemed also to keep her bowels in good condition. I ordered tr. ferri chloridi fifteen drops after each meal, and alternated every three or four weeks with the ferri et quiniæ citr. She certainly improved under these tonics; her catamenia became almost regular. She lost even the slight œdema over the tibiæ, the fluid in the abdomen disappeared, and the walls of the latter filled out with fat.

Besides this I used the galvanic or constant current of electricity for several weeks, but obtained no positive results from it. After a time I tried Fowler's solution of arsenic, but her stomach would not bear it. Having noticed during the first summer how much better she felt in the hottest of days, as soon as cool weather came on I used the hot-air baths under a wire cradle, carrying the temperature to even 125° F. before she would commence to perspire, which seemed to give her considerable relief and kept the skin from being so rough and hard. Sometimes I got a better effect by suspending a damp sponge under the cradle. I have spoken of her constant coryza and bronchitis; nothing seemed to allay them to any extent as long as the weather was cold and wet, and I did not care to give opium.

Under Dr. Minot's advice I used twice only a decoction of jaborandi, but it acted more on the salivary gland than it did on the skin, and made her sick.

When she returned to my care after taking Warner's Kidney Cure for six months she had lost a great deal of ground. I put her upon iron, but its virtue seemed to have gone. Then I ordered a pill containing one twentieth of a grain of strychnia three times a day. A hot-air bath twice a week was advised, but she was so weak they exhausted her a great deal. I can speak very confidently of the benefit derived from hot-air baths and the old tr. ferri chloridi. Perhaps if she could have borne jaborandi well it could have taken the place of the hot-air baths.

The chief centre of the disease was in the throat and neck, though it extended pretty well through the whole system. The immediate cause of death was evidently suffocation, and an accident.

Professor Ord describes the disease as seated in the connective tissues of the body, this being swollen and jelly-like and œdematous with mucin: death is caused by the patient being smothered in his own connective tissue.

There seems also to be a curious resemblance between myxœdema and cachexia strumipriva of Kocher, of Berne, who points out that almost a similar development of symptoms takes place when the thyroid gland has been totally removed.

By the kind invitation of Dr. R. T. Edes I have seen his recent case in the City Hospital, which certainly presented the same characteristic facial expression as my patient, only in a less degree; the eyes pendulous, nose broadened, the lips thick, large, and purple, and the same dusky reddish-purple hue of the cheeks, which gave a great semblance to health. As to the other symptoms, as Dr. Edes has said, they have not developed yet.

The post-mortem examination was made by Drs. Fitz and Whitney at three P. M. December 9, 1883. Rigor mortis present; interior of the body warm.

Skin everywhere unusually pale. Face and upper part of the neck swollen, as if œdematous, but not pitting on pressure. Lips of a pale blue tint. Legs slightly œdematous, pitting on pressure; a moderate quantity of serous fluid escaped from a cut through the skin.

Examination of the brain presented nothing abnormal.

Section through the parietes of the abdomen and thorax showed abundant subcutaneous fat tissue. The voluntary muscles wherever examined were remarkably pale.

The pericardium contained about two ounces of pale yellow fluid. The right side of the heart was distended with dark liquid blood, and the blood throughout the body was fluid. The left ventricle was contracted and empty. The valves and cavities showed nothing abnormal. The muscular substance was of a pale gray color and without microscopic evidence of any degenerative change.

Old pleural adhesions were found at the apices of the lungs. The lower lobes were injected; not œdematous. The bronchi and pulmonary vessels presented no abnormal appearance.

The organs of the mouth and neck were removed subcutaneously. The tongue was symmetrically increased in size, perhaps one half. With the exception of marked pallor of the muscle nothing abnormal was observed on section. Examination of the hardened tongue showed frequent pigmentation of the apices of the papillæ. The œsophagus presented no abnormal appearances.

Larynx small. True and false cords swollen, elastic; glottis narrowed. Section through the swollen mucous membrane showed a homogeneous, glistening, translucent surface, and the swollen tissue did not shrink in the course of twenty-four hours.

Microscopic examination gave evidence of an occasional fatty degeneration of the fibres of the thyro-arytenoid muscle. The sub-mucous tissue of the tongue and larynx gave the reaction of mucin. The larynx was hardened in alcohol, and numerous sections were made through the epiglottis and vocal cords. The results of their examination were for the most part negative. A swelling of the perineurium of a nerve trunk in a vocal cord was noticed.

The thyroid body was so injured in the removal of the cervical organs that an accurate determination of its size could not be made. Otherwise its appearances were not abnormal.

Spleen of normal size, firm, dark red. Details of structure distinct.

Kidneys firm, deeply injected. The surface of the lower portion of the right kidney showed several super

ficial scars. The structure of the kidneys in general presented nothing abnormal on microscopical examination. Bladder contracted; its wall showed nothing abnormal.

Uterus nearly doubled in size; flaccid in region of the internal os. Ovaries large, with numerous dropsical follicles.

Liver large, deeply injected; nothing abnormal observed on section or with the microscope. Pancreas normal.

Stomach empty; its wall presented no abnormal appearances. Lacteals of upper part of small intestine injected. Large intestine greatly distended with gas.

Diagnosis. Enlargement of tongue. Myx(?)œdema of face, neck, and larynx. Vascular engorgement of spleen, kidneys, and liver. Hyperplasia of uterus.

The cause of death was evidently suffocation from swelling of the larynx. The submucous tissue of the latter presented the pale, homogeneous, translucent appearance of ordinary œdema, but differed in its elastic resistance to pressure. The swelling of the cords was regarded as a myxœdema of the larynx. This view is based not only upon the appearance of the swollen tissue but also upon the absence of shrinkage on exposure to the air after a lapse of twenty-four hours.

The determination of the presence of mucin was not regarded as of diagnostic importance, since the intimate connection between the mucous membrane and submucous tissue readily permitted the presence of an apparent excess of this constituent in the removal of fragments for examination.

It is to be regretted that the conditions of the autopsy were such as to prevent a thorough examination of the skin of the neck and face.

A TYPHOID EPIDEMIC AT THE "NORTH END" (BOSTON).[1]

BY W. N. BULLARD, M. D.

I DESIRE at this time merely to give a short description of an epidemic of typhoid fever, which occurred during last autumn and winter at the North End, and which was especially noteworthy from its being so closely confined to the inhabitants of two, or at the most three, houses, and from the fact that in those families which were attacked so few members escaped the disease. In spite of diligent investigation I have not yet been able to satisfy myself in all respects in regard to the origin of the disease and the method of its propagation, but certain conclusions have been arrived at. All the houses were carefully examined many times by the officers of the Board of Health, whose reports I will present later. The instructions of the Board of Health in regard to disinfecting were faithfully carried out, and in most of the later cases extra precautions were used.

HOUSE I.

On the 12th of October, 1883, I was called to a child (boy) of seven years in the family A, living on the ground floor of this house. He was ill with a typical case of typhoid fever, which went through a regular course, and I saw the child every day until his recovery. There had already been a number of cases of sickness in this house, and three persons had died here since the preceding July. The first of these was the mother of the child, aged twenty-eight, who died July 28th. She was attended by irregular practitioners, and the diagnosis in her case was uncertain. The second was the child's aunt, thirty-two years old, living with the family on the ground floor, who died some time in September; and the third was a woman who lived on the second floor (that is, two flights up), the mother of a large family. This family (B) had at the time I was called removed from the house, but we shall hear of them again hereafter. Both these latter women were seen by regular practitioners, and in both cases the diagnosis of typhoid fever was made. In addition to these fatal cases three children in family A had been ill since the summer, but it is doubtful with what disease.

Thus when called to this house there had already been two deaths in the family on the ground floor since the preceding July, one of which at least was from typhoid fever, and one death in family B on the second floor. In addition to this, three children in the first family had been ill. The child I saw recovered in two weeks after a mild attack, but on the 13th of November, just a month from the time when he was taken ill, another child, a girl three years old, was attacked. In her case the disease was very light and she recovered perfectly.

As I have before said the family B had moved out of the house some time in October, and their rooms were occupied by a large family, most of whom had only lately (within three months) come from Ireland. This family consisted, when they moved into the house, of the mother and six children (five girls and a boy), an aunt, and a cousin (a young fellow who left the house shortly afterwards). The family, or most of them, had previously lived in a house in Foster Street in which there had not been any cases of fever, nor were there any there subsequently. On the 30th of November, about two weeks after the second child in family A was taken ill, I was summoned to this family. One of the children, a girl of thirteen, was then sick with typhoid. Exactly two weeks later the mother, aged forty, and a daughter of seventeen, were taken ill, and within three days thereafter a son (twenty) and a third daughter (eleven). On the 30th of December, again in two weeks, the fourth daughter was attacked with typhoid, and on January 23d the fifth and last. The only members of the family who escaped were the aunt, a woman of about thirty-five, and the cousin, who left the house shortly after the first child in this family was attacked. In the family on the ground floor the two adult men and the grandmother alone escaped. (It is possible that some of the children in this family did not have typhoid.) The family on the first floor consisted only of adults, a man and his wife, and were not affected.

In connection with this house, I should say that on the 3d of January a man of twenty-one was attacked with typhoid fever in the house in the rear of the one we have been considering. He was sent immediately to the Massachusetts General Hospital, where he recovered, and there were no more cases in that house.

HOUSE II.

(1.) This house, like the previous one, was on —— Street, and separated by only one house from House I. On the 26th of October, that is, about a

[1] Read before the Section for Clinical Medicine, Pathology, and Hygiene, of the Suffolk District Medical Society, May 14, 1884.

fortnight after my first case in House I., I was called to the family on the first floor (one flight up) of the house, family D. The family were cousins of family A, and consisted of husband and wife, six children, and a young man, nephew or cousin. At this time the husband, aged forty, and three children, fourteen, eight, and six years old respectively, were ill. They all presented typical symptoms of typhoid fever, the man's case being a severe one. Again, about fifteen days after, that is, on the 12th of November, another child, eleven years old, was taken ill, and the next day the fifth child (five); one week later the young man, twenty-one years old. All these cases were treated at home, and all recovered. Of the whole family of nine persons only two, the mother and the baby, were unaffected.

(2.) At the same time that this family were so ill (about the 1st of November) the family above them, that is, on the second floor, was attacked. This family was made up of four persons, husband, wife, and two grown-up sons. The wife, aged sixty, was first taken ill and died. The son, twenty-two years of age, had typhoid shortly afterwards, and was sent to the hospital, where he recovered. These cases were not under my care, but were seen by a regular physician.

(3.) On the ground floor of this house lived an Italian barber with his family (wife and child). He moved away from the house about the 1st of November; was taken ill in his new residence on Endicott Street on the 21st of November; was sent to the City Hospital and recovered. His wife and child were not affected.

HOUSE III.

(1.) We will now return to the family B, who had formerly occupied the second floor of House I., but who, after the death of the wife, had removed. They took the ground floor of this house (House III.), which was several blocks distant from their previous residence. On the 7th of September a woman had been taken ill with typhoid fever, and had subsequently died in this house. Since then there had been no cases of sickness in the house. About a fortnight after the entrance of family B into this house, namely, on the 16th of October, I was summoned to see a sick boy (eleven) in this family (B). He was found to have typhoid fever, and the disease ran the ordinary course, ending in recovery. About a month later I found the father, a man of forty-three, a worker in the gas house, and the other three children, all boys, aged respectively five, six, and eight years, ill with the same disease. They were all sent immediately to the hospitals. A week later the hired woman, who had cared for the children, and washed their clothes, was also attacked. Thus in the family, consisting of husband, wife, and four children, every member had typhoid fever, and also the hired servant who lived with them a part of the time. This was, perhaps, the most striking evidence in favor of the contagiousness of the fever.

(2.) One flight above family B, in House III., lived a man and his wife with two young children, one a baby. On the 9th of November, that is, while those below were ill, the oldest child, a boy of five, was seized with the fever. His case was a typical light one, and he recovered well. On the 24th of November, just as he was thoroughly convalescent, his father, a man of thirty-two, was attacked. In his case the fever was severe, as he had been addicted to the use of stimulants, but he also recovered so as to be nearly well by the time that his wife, a woman of twenty-eight, took the disease (December 21st). She died in the hospital. Two or three days after the mother had become seriously ill the baby died, but probably not of typhoid. In this family of four, three were affected with the disease, and only the baby escaped. The baby's grandfather also lived in this house, but not in the same rooms. He died also suddenly about the 15th of December, but probably not of typhoid.

(3.) On the same floor as the last family was a family consisting of father, mother, baby, and, possibly, another child. They moved to another house temporarily about the middle of November, but were obliged to return again on account of sickness in their own family. None of this family had the fever.

TYPHOID FEVER.

[1] Removed from house about November 1st.

[2] Removed here from House. I.

(4.) In the family where the husband and wife were taken ill in succession [see (2) above], the wife was left for a time without proper attendance. One of the neighbors consequently, living in the next house, came in once or twice a day for two or three days to render her what assistance was in her power. About ten days afterwards both she and another woman living in her house were taken ill with the fever. Of these patients one died and one recovered.

To resume, in this house, containing three families, numbering in all fourteen or fifteen people, there were eleven dwelling in the house the whole time. Of these eleven, nine were attacked with the fever, and the two others both died of other troubles while their relatives were still ill. Those persons who were in the house only a portion of the time escaped, but two persons were attacked in the next house in which there had been no fever previously.

As a total, then, in these three houses we have thirty cases of typhoid fever, and if we add one case which was taken ill just after leaving one of these houses, and three cases in the adjoining houses, we have in the whole thirty-four. Out of these, twenty-eight were under my care for either the whole or a part of the time. The total number of cases under my care between October 12, 1883, and January 23, 1884, inclusive, at which dates the first and last of the cases in the houses under consideration were noted, was forty-five, leaving seventeen cases in the North End not included in the cases mentioned. But of these seventeen, four cases were in all probability connected with those described, three being in the family of a woman who had washed clothes for family B, and the fourth case being a girl of twenty-two, a cousin of family D. Out of forty-five cases of typhoid fever under my care there were, therefore, only thirteen in which no connection with these houses could be traced.

Out of sixty-seven cases, all that were reported from this portion of the North End within this period, we find but twenty-four not plainly connected with one of these houses.

Such an epidemic as this seems to me to point very clearly to the contagiousness of typhoid fever, particularly in the case of those naturally disposed to it. There can be no doubt but that, as Pfeiffer has lately pointed out in the *Berl. klin. Wochenschrift*, certain families possess a special immunity in regard to this disease, while in others perhaps there is a certain predisposition towards it. In these houses there were two families which entirely escaped, one of which, however, was away from the house a portion of the time, and the other consisted only of adults. There was one family in which there was only one case, but this family had already removed from the house when this case occurred. There was one family (all adults) in which there were two cases, one in which there were three, one in which there were four, and three in which there were seven.

As to the cause or origin of this epidemic, I have at the present moment nothing to say, but if any positive conclusions can be drawn from our investigations I shall hope to bring them to your notice at some future time. I will, however, say a word in regard to some of the ways in which this may have spread. In all these cases, except perhaps the very first, precautions were taken in regard to the water-closets or vaults and the excreta of patients. The Board of Health was of course informed of every case as it occurred, and examined the houses repeatedly, with the results to be given. In House I. the water-closet was outside and apart from the house.

In two at least of these cases the disease seems to have been obtained from washing the clothes of patients. This was probably the case with the servant in family B, and very possibly also in the case of the family who likewise had the fever after the mother had washed for one of these families. In the latter, however, it was not the mother who had the fever first, but one of the children.

(In a Portuguese family, which had the fever a little later in another part of —— Street, the disease in a young girl, the last of the family who had it, seemed directly traceable to her having washed the clothes of those ill previously.)

In none of these cases could the patient be isolated from the rest of the family. At the most there were only two sleeping rooms and frequently only one.

Before closing, I desire to express my thanks to the Board of Health of the city of Boston for their kindness and courtesy in permitting me to make use of their records and rendering me all the assistance in their power.

The conclusions to be drawn from this epidemic seem to me to be —

(1.) That we cannot be too careful in using every reasonable means to prevent the spread of typhoid fever, and not confine ourselves exclusively to care in regard to the excreta.

(2.) That although in ordinary cases typhoid fever is not an extremely contagious or infective disease, yet that under certain conditions at present not well understood it may become so.

(3.) That special attention should be paid to the washing of the clothes of patients, more especially of any which may be stained or soiled by their excreta.

(4.) That great care should be taken to disinfect the chamber vessel or pail used by the patient, and that no other member of the family should be allowed to use it under any conditions.

Reports of the Board of Health.

HOUSE I.

In March, 1883, foul and offensive vault and filthy cellar. Found in good condition April 30, 1883. Since then nothing wrong could be detected.

HOUSE II.

Nothing wrong discovered at any time.

HOUSE III.

May 24, 1883. An offensive and defective vault, also a defective waste conductor in passage-way under house. The waste water runs into the passage-way.

July 23d. Now in fair condition. Do not think there is sufficient cause for further action.

November 14th. Drainage defective. Traps needed to sinks. Vault in fair condition. Drain open in passage-way under house at foot of waste conductor.

December 5th. Nothing done.

January 1, 1884. Work not yet begun.

January 10th. Drainage defective. Traps supplied to sinks to-day. Vault offensive. Odors from vault and open drain in passage-way under house. There is general want of cleanliness in the house.

April 16th. Drain in passage-way obstructed. Water backs into basement.

HOUSE ADJOINING HOUSE III.

January 3d. The waste pipes from sinks empty into defective wooden conductors, which should be removed and tight pipes with traps put in. An apron should be put in under the privy seats to prevent the filth from lodging on the sills, and the vault should be deodorized.

February 16th. All right.

REPORT ON OBSTETRICS.

BY C. M. GREEN, M. D.

THE INFLUENCE OF PUERPERAL EPIDEMICS ON THE TIME OF DELIVERY.

AT the meeting on November 6, 1883, of the Académie de Médecine, M. Hervieux made a communication [1] relative to the influence of puerperal epidemics on the time of delivery. It has long been known that a certain number of pregnant women are liable to contract a puerperal septicæmia, which sometimes limits itself to provoking premature labor and sometimes develops itself with all its characteristics after the premature expulsion of the fœtus; but these cases have always been considered as exceptional. In the opinion of Hervieux, on the contrary, it is the exception for a pregnant woman to live in an infected place without being herself infected: he has been led to this conclusion by observations made at the Paris Maternité during more than twelve years.

The puerperal poison acts here like other poisons, and it is known that toxic maladies which affect pregnant women do not always act on the mother and on the fœtus in the same way, variola for example. In his treatise on Abortion, M. Garimond has given infection and contagion as the probable causes of miscarriage in many cases, without giving any clinical demonstration in support of his opinion. This clinical evidence M. Hervieux has now presented to the Academy. In his opinion, the more a pregnant woman lives in an infected place, the more liable is she to premature delivery: Hervieux therefore believes that in times of puerperal epidemics every maternity should be closed to pregnant women, and that even when there is no epidemic the entrance to hospital should be deferred until the woman is as near as possible to full term.

FORCEPS IN BREECH PRESENTATIONS.

Dr. Truzzi [2] believes that in cases of impaction of the breech in the upper or middle parts of the pelvic cavity, when a hip has not yet rotated to the pubic arch and the speedy extraction of the fœtus is necessary, it is safer to resort to forceps, when traction with the fingers fails, than to attempt extraction with the blunt hook or fillet. He thinks it is safer and easier to apply the forceps to the sides of the fœtal pelvis than to the sacrum and an opposing thigh; as, when applied in the latter way, the forceps are more likely to slip and to injure the abdomen or its contained organs. The iliac bones are elastic at this period and well protected by soft parts; so that even if the amount of compression is somewhat excessive, Truzzi believes it is almost impossible to injure the fœtal pelvis. The forceps blades are passed so that the tips extend above the iliac crests: when traction is made the tips of the blades bury themselves slightly in the parietes and obtain a firm hold over the innominate bones. The liver is above reach and the intestines from their great mobility easily elude compression. A folded towel should be placed between the handles when otherwise the compression would be too great. Truzzi has never seen the forceps slip when applied in the manner described to sacro-anterior positions.

PERITONITIS DEVELOPED DURING PREGNANCY.

Megrat [3] has collected thirteen cases of peritonitis developed during pregnancy, seven of which were observed by himself, and has described at length the ætiology, course and treatment of the affection, and its influence on the course of pregnancy and on the life of mother and fœtus.

Peritonitis in pregnancy is quite rare, at least attention has been called to it hitherto only by Schröder and Scanzoni. Of the thirteen mothers seven died: only two went to full term, the others aborted in the fifth, sixth, seventh, and eighth months. Of twelve embryos ten perished, partly on account of the peritonitis, partly by abortion.

Regarding the ætiology of the affection, the efficient cause is not always disclosed by the autopsy: there may be ruptures of the tubes, or rupture or inflammation of complicating ovarian cysts. There may be circumscribed foci of inflammation in the gravid uterus, with purulent softening and perforation into the peritoneal cavity: extension outward of the inflammatory process of an enteritis, and finally "taking cold" are mentioned as further causes. The severity of the affection depends upon its cause. If on account of rupture general peritonitis arises, the prognosis is very bad and death may occur in a few hours; if the peritonitis remains circumscribed, the prognosis is naturally more favorable.

As regards the symptoms, they are those usually characteristic of peritonitis, — extreme abdominal pain, tympanites, vomiting, collapse, and diarrhœa or constipation. Therapeutically Megrat employed cold, opiates, abstraction of blood, mercurial inunction, quinine, and carbolic acid in pill form.

Peritonitis appears in general to exercise a deleterious influence on the continuance of pregnancy, and on the other hand the complicating pregnancy aggravates peritonitis to a considerable degree. After the emptying of the uterus a sudden and considerable improvement of the inflammation was observed. The influence on peritonitis of the expulsive efforts of the uterus is a various one: on the one hand they appear to increase the inflammation; on the other, after the expulsion of the fœtus, there is an improvement in the symptoms. As a result of his observations Megrat cannot express himself as absolutely in favor of rapid, artificial termination of the pregnancy, since the result may be directly fatal.

THE USE OF IODOFORM SUPPOSITORIES FOR INTRA-UTERINE TREATMENT IN THE PUERPERIUM.

Ehrendorfer, assistant in Professor Späth's clinic in Vienna, in a recent paper,[4] advocates the use of iodoform suppositories, in preference to other methods

[1] Archives Générales de Médecine, December, 1883.
[2] Gazz. Med. Ital. Lombardia, Aug. 4–18, 1883, and the London Medical Record, Jan. 15, 1884
[3] Annales de Gynécologie, No. 10, 1883, and Centralblatt für die Medicinischen Wissenschaften, No. 10, 1884.
[4] Archiv für Gynäkologie, Band xxii., Heft 1.

of administration, in cases which require, for prophylaxis or otherwise, intra-uterine antiseptic treatment in the puerperium. When used in the form of a solution, the greater part of the iodoform soon flows out of the puerperal uterus and no lasting effect is obtained: if the drug is applied by insufflation, Ehrendorfer believes there is danger from the introduction of air: by the use of suppositories this latter danger is avoided and the endometrium is not irritated by the introduction of an intra-uterine tube. Ehrendorfer's method of using iodoform possesses one very great advantage over the customary intra-uterine treatment with carbolic acid, namely, that the patient is much less frequently disturbed, as the suppository melts slowly and its effects are therefore more lasting: in cases where there are tears of the vagina and perinæum, which have perhaps required the introduction of sutures, this is an advantage of some importance.

Regarding the composition of the suppositories, Ehrendorfer believes that oil and cacao-butter are objectionable, since they are liable to become rancid and irritating: he therefore uses gum-arabic, glycerine, and starch in equal parts as the excipient mass, his formula being

Iodoformi pulv.	20.0
Gummi Arabici	
Glycerini	
Amyli puri	ää 2.0

Ft. suppos. no. 3, longit. cm. 5-6.

Each suppository contains, therefore, a little over ninety grains of pure iodoform; but Ehrendorfer has never observed any poisonous effects from the use of as much as one hundred and fifty grains. Before the insertion of a suppository the uterus should be washed with an aseptic fluid: the suppository may then be introduced with a dressing forceps.

THE INFLUENCE OF AGE ON THE LABOR OF PRIMIPARÆ.

Kleinwächter has studied this subject very thoroughly, not solely with reference to the length of labor, but with a view to determining the relative liability of primiparæ of various ages to antecedent menstrual disturbances, to the various accidental complications of pregnancy and to puerperal disease. He has also investigated the relative necessity of instrumental interference, relative morbidity and mortality, the liability to abortion, and the influence of the mother's age on the sex and weight of children. The material for study Kleinwächter found in the records of 920 cases of primiparæ in his clinic at Innsbruck. These cases he divided into three groups, namely,—

I.	16–19 years of age:	111 cases.
II.	20–29 years of age:	694 cases.
III.	30–41 years of age:	115 cases.

These groups he designated as the young, the middle-aged, and the old, respectively. From his study of these cases Kleinwächter draws, among others, the following conclusions:

(1.) Accidental complications, which have nothing to do with pregnancy, occur least often in the youngest primiparæ and most frequently in the old.

(2.) Ailments attributable to pregnancy are observed most frequently in the old and next most frequently in the young.

(3.) Hæmorrhages in the course of pregnancy occur most frequently in the young and least frequently in the old.

(4.) The duration of labor is most frequently abnormally protracted in the old: in this respect the young stand next to the old.

(5.) Inefficient pains, on account of which the duration of labor is abnormally protracted, are least often observed in primiparæ in the bloom of their sexual life, i. e. from 20–29, and most frequently in the old.

(6.) Therefore forceps must be used most frequently in the old and least often in the middle-aged.

(7.) The lengthening of the labor of primiparæ with the increase of age occurs chiefly in the first stage: the second stage is scarcely affected by differences of age: the third stage is not at all affected.

(8.) The mortality per cent. after forceps operations on primiparæ rises parallel with the increase in age.

(9.) The older the primipara, the greater is the danger of perinæal laceration.

(10.) The older the primipara, the more likely a post-partum hæmorrhage, although the frequency of hæmorrhage is by no means so great as hitherto supposed.

(11.) With increase of age increases the disposition of primiparæ to affections of the kidneys.

(12.) The frequency of œdema without kidney disease also increases with the age.

(13.) The older the primipara, the less the danger of mastitis, and the less also the likelihood of her ability to suckle.

(14.) The old most frequently, the middle-aged least frequently, sicken and die of puerperal fever: the same is true of puerperal mania.

(15.) The morbidity and mortality per cent. is highest in the old and lowest in those from 20 to 29 years of age.

(16.) Spontaneous premature labor occurs very frequently in old primiparæ, and least often in the middle-aged.

(17.) With increase of age the frequency of abnormal positions of the fœtus increases.

(18.) The older the primipara is, the more likely is she to bear a boy, except only those from 20 to 21 years of age, who bear more girls than boys.

(19.) Analogous to the discovery made by Hecker and confirmed by Wernich, that first-born children are heavier and longer the older the mothers are, is the fact that the umbilical cord of the first-born of old mothers falls off the earliest, and that of the first-born of the youngest mothers the latest.

(20.) The liability to twin pregnancy in primiparæ increases with their age.

(21.) With increase of age in primiparæ the frequency of bearing deformed children diminishes.

(22.) The mortality per cent. of first-born children increases with the mothers' age: among the oldest primiparæ the fœtal mortality reaches a not inconsiderable height.

[1] Zeitschrift für Geburtshülfe und Gynäkologie, Band x., Heft 1.

—Some of those who are horrified at vivisection, but look upon hunting and fishing with complacency, may read with profit these words of Pasteur: "Never have I had the courage to kill a bird in hunting; but when experiments are concerned no scruple stops me. Science has the right to invoke the supremacy of the end."

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

MAY 14, 1884. Meeting called to order at eight o'clock. DR. R. T. EDES in the chair.

The SECRETARY read an invitation to the Society to visit the Institute of Technology May 15th to listen to a description of the new system of heating and ventilation which has recently been introduced there, and to inspect the Rogers Building, where the system would be in operation.

The first paper was by DR. E. G. WEST, entitled

A CASE OF MYXŒDEMA, WITH AUTOPSY.[1]

Dr. West remarked that no pathological changes were observed macroscopically in the tissues of the brain, in the organs of the chest or abdomen. The blood presented a marked degree of fluidity, due, doubtless, to the accident which killed the patient, and appeared the same as in ordinary cases of suffocation or strangulation. The muscular tissues were everywhere very pale, almost white, so that these structures resembled the flesh of veal.

DR. EDES stated that the paleness in color of the muscular tissues was not due to fatty degeneration of the fibres either in the voluntary muscles or in the heart. There was slight serous (ordinary) œdema of the limbs, and a small degree of pitting could be noticed after prolonged pressure. The mucous œdema was still present in the face and members after death, and was especially developed in and about the folds of the larynx. Here the mucous membrane was full and baggy, and no doubt was the immediate cause of death. At the autopsy these portions of larynx were incised, and after some hours no reduction in size or collapse of œdema could be observed. Under the tongue the tissues were especially swollen and œdematous from the accumulation of mucin.

DR. WHITE stated that the case seemed to be a typical one in all respects. He questioned the accuracy of the generally received opinion that the disease has not been observed in the male sex; and the utility of attempting to stimulate the action of the sweat glands, as they had often been found atrophied in the changes which the skin undergoes in advanced myxœdema. He doubted, too, the correctness of the statement that the disease was always or generally preceded by a mental or nervous shock. It appears to be more prevalent in some countries than in others, as seven cases were exhibited at the last meeting of the International Medical Congress in London, whereas a recent statement had been made that no case had as yet been observed in Vienna. Two cases had come under his own observation in Boston during the last five years.

DR. EDES remarked that the reader was not quite correct in supposing this to be the first case in this country followed by an autopsy.

Dr. Elizabeth M. Cushier had reported a case, with a very careful autopsy, in the *Archives of Medicine*, viii., 1882, December. The cutaneous and subcutaneous tissues had undergone characteristic changes, and in addition there was well-marked degeneration of the spinal cord.

In reference to the remark made by Dr. White that no case of this kind had been seen in Vienna, it would be interesting to observe its relative prevalence in different nationalities in this country. It is certainly not confined to the British races. One patient seen by Dr. Edes was of Norwegian birth.

Mental shock is not a universal accompaniment or forerunner of myxœdema. In one special case no such accident could be remembered. In another case which has lasted fifteen years, and is still living, no mental shock has ever been known to occur. In this patient the hands are immensely swollen, and are unsightly and disfigured both in form and color, and the disease is evidently slowly but certainly progressing toward a fatal termination.

DR. E. T. WILLIAMS asked if any amelioration was noticed after the use of diuretics.

DR. WEST replied that the serous œdema of the lower extremities entirely disappeared, and the patient experienced a great degree of relief from the heaviness and fullness which this had occasioned.

DR. PRINCE asked if any increase in the fibrous tissue of the parenchymatous organs was noticeable, and stated that Dr. John Harley had observed this in all the visceral organs, and had also made the assertion that in these cases there was well marked and frequently quite extensive degeneration of the ganglia of the sympathetic nervous system.

DR. EDES remarked that although attention has been directed to these cases only within a few years there is no reason to suppose that the disease is one of recent origin. Cases have doubtless existed in the past, but have been confounded with other diseases. It is not necessarily so rare a disease as it would seem to be because the majority of cases would undoubtedly be mistaken for some affection of the liver or kidneys. In point of duration, course of symptoms, and termination, however, there is very little similarity with the progress of either of these diseases.

The second paper was by DR. W. N. BULLARD, upon

AN EPIDEMIC OF TYPHOID AT THE NORTH END.[2]

DR. PRINCE opened the discussion as follows: —

The epidemic which has been so carefully studied and reported by Dr. Bullard is very valuable from the fact that it is one which shows almost conclusively the communicability of this disease under certain conditions. The difficulty with most epidemics is that it is generally impossible to exclude the possibility of all the cases having contracted the disease from the same source, but in the epidemic just reported it can hardly be believed that the inmates of houses No. II. and III., at least, could have contracted the disease otherwise than on the theory of contagion. It is on the evidence of such epidemics that we rely for our belief in the communicability of the disease. There is one fact which is always referred to as evidence against the contagiousness of typhoid, to which, it seems to me, too much prominence has been given, and that is, the fact that the disease is rarely communicated from one patient to another or to attendants in hospitals. I am unable to see any reason why much weight should be attached to this. For let us suppose that it was proven by experimental evidence, as I believe it has been by clinical evidence, that the stools contain the

[1] See page 49 of this number of the JOURNAL.

[2] See page 53 of this number of the JOURNAL.

poison, that the germs have been isolated and shown to be capable of successful inoculation in a healthy person, how could we expect that under the conditions by which a patient is surrounded in a hospital the stools would be capable of infecting others in the hospital? I hold not. In the first place the poison is mixed with semi-liquid matter, and consequently prevented from impregnating the atmosphere. The vessels are quickly emptied and washed before the fæces become dry, etc., etc. Let, however, the stools become dry and pulverized, and a medium of contagion immediately is furnished. The atmosphere may take up the poison in this dry, dust-like form, and infection result. It is these conditions that exist in tenement and other houses, where the facilities for caring for the excrement are insufficient. It may be that a secondary fermentative process is necessary for the discharges to become poisonous, but this theory is neither absolutely necessary to explain the facts thus far known nor is the fact yet established, though it may prove to be true. It is upon the study of epidemics that we rely to show the poisonous nature of the stools of typhoid patients and the possibility of contagion. The evidence furnished thus far by experiments on animals has been unsatisfactory.

It may not be out of place here to mention the results of some experiments which Dr. Bullard and myself have conducted during the past winter, with a view to determining this point by direct inoculation. The animals chosen were rabbits, and the experiments divided into two sets.

For the first we obtained some liquid stools from a patient ill with typhoid. The stools were strained through coarse cotton cloth, and about fifteen minims subcutaneously injected into each of five rabbits. In all the animals fever developed, but no diarrhœa or any other definite symptoms. The animals were killed at the end of from three to five weeks. No lesion of the intestines or of any other organs was found. One animal died the second day after inoculation. Unfortunately the body was thrown away by accident before it could be examined. The animal could not, however, have died of typhoid.

For the second set, the tissue about the edges and base of several intestinal ulcers from a patient who had died of typhoid fever was obtained through the kindness of Dr. Gannett, who made the autopsy. The lesions of the intestines were very marked and typical. The tissue thus obtained was cut into very fine pieces, macerated and bruised in about a teaspoonful of water till the tissue became white and mere pulp, then strained through coarse cloth and injected, in divided portions, under the skin of four rabbits. Fever developed, though not very high. No other symptoms. The rabbits were killed at varying periods. No lesions found after death. The results of these experiments were accordingly negative, and correspond with those obtained by other experimenters.

Küchenmeister, as long ago as 1850, reported an epidemic amongst rabbits which he regarded as probably typhoid fever. The principal anatomical changes which he found were infiltration of Peyer's patches, swelling of the mesenteric glands, and enlargement of the spleen, but no ulceration of the patches.

These changes resembled those found by Birch-Hirschfeld as a result of the infection of rabbits with typhoid stools. Birch-Hirschfeld made four different sets of experiments: —

In the first large quantities of typhoid stools were injected subcutaneously, and though the rabbits rapidly became sick, had fever, and when the quantity injected was particularly large, died, no lesions were found in the intestine.

Second. Blood from a person who had died of typhoid was injected subcutaneously. No alterations were found in the intestines.

Third. Typhoid discharges were introduced by the mouth. The result varied according to the quantity given. When the quantity was small, some of the rabbits remained perfectly well, others had fever, diarrhœa, and lost flesh, nine died. Those killed had slight swelling of Peyer's patches, but no swelling of the spleen. When large quantities were given the animals exhibited high fever, considerable emaciation, marked diarrhœa; in some cases the fæces were yellow, bad smelling, and pasty. In those which died there was found more or less pronounced swelling of the follicles, especially in the neighborhood of the ileo-cæcal valve and vermiform appendix. In two cases there was found beginning *ulceration* of a Peyer's patch. There was also found more or less swelling of the spleen, infiltration of the mesenteric glands, sometimes pneumonia. No difference was detected between the effect of fresh stools and those kept from two to six days.

Fourth. A rabbit was fed on a small quantity of the tissue from a typhoid ulcer which had been removed five hours previously from the cadaver. The animal exhibited high fever for several weeks. At the autopsy there was found *an ulcer of the size of a pea, of a Peyer's patch* situated at the ileo-cæcal valve. The surrounding tissue had a reticulated appearance, as well as that of the vermiform appendix. Beautifully reticulated appearances in the upper part of the small intestine; follicular catarrh of the cæcum and ascending colon. The other organs normal.

Although these rabbits showed some symptoms analogous to those of typhoid, the last experiment alone gave anything like positive results, and the rabbit which was the subject of this experiment was fed not on typhoid dejections, but on the tissue from typhoidal ulcers.

Bahrat later experimented on fourteen animals. In ten typhoid excreta were introduced into the stomach by means of a catheter, and in four the experiments were conducted so as to test the theory of infection through the air. The rabbits were placed over sand impregnated with typhoid dejections, over the sand was placed a layer of hay so as to prevent actual contact with the dejections. In both cases the results were negative.

Letzerich again injected four rabbits with typhoid stools. The first was killed fourteen days after the injection. The duodenum and the upper part of the small intestine were filled with turbid yellow fluid. The follicles were infiltrated. The second died twenty days after the injection. The duodenum and the small intestine were filled with the same material. The follicles of Peyer's patches were swollen and infiltrated. The third died twenty-one days after the injection. The content of the small intestine was the same. The follicles were swollen and infiltrated, in some places ulcerated. In the fourth (which died forty-eight days after the injection) the duodenum was red, the upper part of the small intestine dark red, the lower portion brown red. The content of the upper portion consisted of turbid yellow fluid; that of the lower portion

of an intensely red fluid containing fibrinous flakes' Follicles mostly ulcerated. The third and fourth had fever and diarrhœa.

Murchison fed a pig for six weeks on fresh dejections without result.

Klein fed monkeys and white mice with milk with which typhoid dejections had been mixed. Results were negative.

Motschutkoffsky tried experiments on men and animals (apes, rabbits, dogs, and cats). He made repeated and thorough inoculations from patients with typhoid and typhus fever without success. His method of inoculating or what was inoculated are not given, but with relapsing fever he employed blood, milk, sweat, urine, saliva, and excrement, and was successful (with which?).

It appears then that only two experimenters, Letzerich and Birch-Hirschfeld, have succeeded in infecting animals with any disease resembling typhoid by means of the stools, and considering the small number of animals in which positive results were obtained and the failure of all other experimenters, it may be questioned whether the disease produced in these cases was real typhoid. The question must still be considered an open one. While successful inoculation would prove the poisonous nature of typhoid stools, failure does not show the contrary. There may be several causes of failure. In the first place animals, as with cholera, may not be susceptible to typhoid. And in the second place, though typhoid stools may be poisonous at certain stages of the disease, it does not follow that they are at all stages, and there is no means of knowing which is the poisonous period, consequently any given stool may or may not contain the poison.

This latter difficulty, however, would not obtain when the tissue from a typhoid ulcer was employed for inoculation, as in our second set of experiments, which would seem to indicate that, unless some secondary fermentative process was necessary for the development of the poison, rabbits are not susceptible.

The difficulty of eliminating other forms of poisoning from the inoculation of such stuff as excrement and necrosed intestinal tissue is obvious.

DR. BLODGETT remarked that grave doubts had been justly raised against the conclusions from experiments upon animals by the inoculation of zymotic diseases, from the fact that very frequently no proper precautions have been taken to prevent the introduction of other than the desired virus, and, therefore, some other disease might be implanted at the same time, and thus either modify or entirely prevent the normal development of the desired disease. Again, in cases in which unwilling animals have been forced to swallow the dejections of typhoid fever or parts of ulcerated human intestine it would certainly not be surprising if the disgust and repugnance of the animal to this offensive procedure, together with the loss of appetite and disturbances of digestion or diarrhœa, which might very probably follow such a repulsive experiment, should occasion appearances within the alimentary canal which might in some degree resemble those of typhoid fever in man. But such results should be very cautiously received on account of the great chances of error due to the circumstances mentioned, as well, no doubt, as to other conditions which might arise from the manner more than from the matter of the experiment.

Another frequent source of fallacy in the subcutaneous injection of the products of disease is the frequent occurrence of a train of symptoms of severe character and fatal termination which bear some resemblance to the phenomena of human typhoid, but are due solely to septicæmic processes which are occasioned by the presence in the tissues of a confined animal of foul, decomposing, often necrosed, portions of another animal, namely, man, who has died from an acute infective disease which has deranged the nutrition and modified the organic character of every part of the body. The occurrence of serious disease and frequently of death from this cause is not considered strange in cases of accidental infection in man, and there would seem to be no good reason why the same thing might not take place in the lower animals under circumstances so much more dangerous than could possibly occur to man. Under these conditions we should naturally expect to find the glands everywhere enlarged, and it would occasion no surprise to find ulcerations within the bowel, which might quite probably be due to tuberculosis or some other foreign process, but to an incautious or enthusiastic experimenter might seem to indicate the successful transplantation of another of the exanthematic processes affecting the human race into the organism of an animal subjected to experimental study.

While fully recognizing the great value of experimental pathology, which is daily assuming a more important relation to human well-being, it becomes doubly necessary to guard against false appearances and erroneous conclusions.

DR. BARNES asked if the vaults were independent of the sewers or were in any way connected with them.

DR. BULLARD replied that he always supposed the vaults to be simple reservoirs for fæcal accumulations, not connecting in any manner with the sewer system. There were no water-closets, they were simply pit privies.

DR. BARNES spoke of the specific character of the poison of typhoid, and mentioned the fact that it is not alluded to as one of the prevailing diseases in China, thus indicating that the virus does not thrive equally well in all parts of the world, but seems to be restricted to certain geographical limits.

DR. EDES suggested that the susceptibility of the entire Chinese race to the disease may have been exhausted in previous ages, and that the present inhabitants of that region enjoy perfect immunity from the ravages of typhoid on account of changes in their organism or physical condition, which have produced a sufficient alteration in the tissues or organs to render them unsuited for the propagation of the typhoid germ.

On motion of DR. HENRY I. BOWDITCH a vote of thanks was tendered the Boston Society of Arts through its secretary, Professor Swaim, for the courteous invitation extended to the Section to attend the next meeting of that Society.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDE, M. D., RECORDER.

THURSDAY evening June 12, 1884. The President, DR. TYSON, in the chair.

SARCOMA OF TESTICLE.

Presented by DR. G. DE SCHWEINITZ.

A. K., aged forty-three, a native of Germany, married, presented himself May 22d in the Surgical Dis-

pensary of the University Hospital for an opinion concerning a tumor of the left testicle, with which he was suffering. His general health had always been good until one year ago, when he first noted a beginning glandular swelling of the left testis. A short time previous to this he had suffered with gonorrhœa, which was followed by an attack of orchitis. He knew of no member of his family that had ever been afflicted with any form of morbid growth. Examination revealed a very large, somewhat pear-shaped growth of the left testicle, over which the skin was freely movable. The veins were much enlarged. The inguinal glands of the left side were also involved, and the thigh and leg of that side swollen from œdema. Above the line of Poupart's ligament both palpation and percussion revealed another mass situated in the left iliac fossa. A very unfavorable prognosis was given, and operative interference not advised. He, however, earnestly begged for the removal of the tumor of the testicle, which caused him severe dragging pain, and incommoded him in walking. The dangers of the operation and the fact that it would at best only be partially palliative were explained to him, and as he still asked for its performance the growth was removed. The case progressed very well for a few days, when he died rather suddenly. Dr. Hughes and myself made the post-mortem examination and found the following conditions: Lungs showed commencing phthisis of apex; left pleural sac occupied by a pint of serum in which floated some flakes of recent lymph. Heart normal; cavities occupied by post-mortem clots. Liver very fatty. Right kidney apparently normal. The retro-peritoneal glands were all converted into a huge sarcomatous mass, as were also the glands and tissues of the left iliac region, and from there the growth passed up to the lumbar region and surrounded, although it apparently did not greatly involve, the kidney. Upon cutting into the tumor of the testicle about a pint of bloody serum escaped from the cavity of the tunica vaginalis. The growth occupies the body of the testis, is soft and friable, in places breaking down, and the cavities thus formed filled with semi-fluid contents. The growth has burst through the tunica albuginea, thus showing the first step in the march of this morbid process up the spermatic cord into the abdominal cavity to the retro-peritoneal glands and other tissues involved by the disease.

Microscopically the tumor is a sarcoma composed of round and spindle cells, which are in relation to the remnants of connective tissue stroma. A very distinct tendency to alveolar arrangement is observable in places. It would probably be classed by some pathologists as an endothelial carcinoma or carcinomatous sarcoma.

DR. SHAKESPEARE said that the history of this case, the post-mortem finding, and the microscopic examination forcibly reminded him of the last discussion by this Society of the same subject. In this case the disease has evidently traveled along the deep lymphatics as far as the retroperitoneal lymph glands of the lumbar region. In this particular it has followed the course of systemic infection pursued by a carcinoma rather than a sarcoma. But it seems to be now well established that the well-known law governing the generalization of sarcomata meets with frequent exceptions in the case of so-called sarcoma of the testicle. Dr. De Schweinitz had spoken of the presence in this tumor of an alveolar structure, and in truth the manner in which the growth had exceeded the bounds of the testicle brings to mind at once the history of an alveolar sarcoma. The reporter had spoken of that tumor as "an endothelial sarcoma." Dr. Shakespeare objected to this use of the term "endothelial," and thought that the tumor in question would be more properly defined as "an alveolar sarcoma." He thought that the term "endothelial" was most commonly applied to carcinomata of certain kinds rather than to sarcomata, and did not think that the tumor named by Klebs "an endothelial carcinoma" differed from other genuine carcinomata in the form or nature of its cells and alveolar structure, but only in the fact that it may originate or be propagated in the lymph spaces or channels. If the term "endothelial" be insisted upon in this case, why not call the growth "an endothelial carcinoma"? This naturally raises the question of pathogenesis. We are told that the testicle is a derivative of the mesoblast. If this be true here is ground for debate as to the proper name to give a tumor of the testicle which has an alveolar structure and a clinical history analogous to that of true carcinoma. He who believes that true carcinoma never has a real connective tissue origin will not consent to call such a growth of the testicle a carcinoma unless he can satisfy himself that, by some chance, a few epithelial cells from the blastoderm have become misplaced in the process of development, and have remained here to form a nidus of a future carcinoma. Malignant tumors of the testicle seem to occupy an anomalous position. They are called sarcomata in the main, and yet, as a rule, their clinical history does not correspond to the sharp outlines which comprise this class of tumors in other localities. On the whole Dr. Shakespeare was inclined to agree with those writers who accepted in general a connective tissue origin for true carcinoma in contradistinction from the epithelial origin of true epitheliomata, and therefore saw no well grounded objection to applying the name of true "carcinoma" to those growths of the testicle which present a typical clinical history and anatomical structure of carcinoma, although they may spring from connective tissue. As bearing upon the subject of pathogenesis of carcinoma he referred to the observations of a few authors who deny the pure epithelial origin of some glandular structures, mentioning in particular the opinion of Creighton, who, after a careful and extensive series of observations on the development and involution of the mammæ, concludes that the acini of this gland are not developed from the cutaneous epithelium but are derived from the connective tissue.

ANEURISM OF THE LEFT VENTRICLE COMMUNICATING WITH THE AORTA.

Presented by W. E. HUGHES.

J. C. W., aged thirty-nine years, a ship carpenter, was admitted to the University Hospital, under the care of Dr. E. T. Bruen, March 6th. He had always worked hard, been much exposed to the weather, was a fairly temperate man, and had never had syphilis. He had had several slight attacks of articular rheumatism, but during none of these attacks had there been any symptoms referable to the heart. There was nothing of moment in the family history. Three years ago his strength, which had never been excessive, failed somewhat, and it became impossible for him to work constantly. There was with this failure of strength more or less dyspnœa on exertion, with a tendency to take cold on any slight exposure, but no

pain over the heart, and very little palpitation. Six months ago he was very much exposed, and since then has been much worse, palpitation now for the first time becoming troublesome. When first seen the slightest exertion caused the most intense dyspnœa and very annoying palpitation; his hands and feet were congested, and his lungs filled with moist râles. The apex beat of the heart was in the fifth interspace, in the nipple line, its action strong and heaving. Over the aortic cartilage could be heard a strong, blowing, double murmur. He died April 6th of gradually increasing dyspnœa, due apparently to congestion of the lungs. He had never complained of pain about the heart. There had been no œdema.

Autopsy by Dr. Barber six hours after death. Pericardium normal. Heart large; its left ventricle moderately hypertrophied and dilated; right normal. Muscular tissue apparently normal. Between the posterior leaflets of the aortic valves was an oblong opening, with smooth, rounded edges, extending a quarter of an inch above the point of juncture of the leaflets with the aorta, and one half an inch below into the wall of the left ventricle, much wider in the ventricular than in the aortic wall. The opening prevented the closure of the leaflets, holding them at least one quarter of an inch apart, and permitting free regurgitation of blood into the ventricle. The leaflets were attached along the opening, in fact, above they formed its edges. This opening led back into a cavity, about as large as a walnut, lying between the base of the aorta and the upper part of the left ventricle on the one hand, and the right auricle on the other, bulging it decidedly into both auricle and aorta. Its lining membrane was continuous with the endocardium, and was thickened and roughened, but not calcareous. The endothelium of the posterior wall of the aorta covering the projection was also somewhat thickened and roughened. Between the upper part of the sac and the aorta where the separating tissue was very thin, composed apparently of only two layers of endothelium, there was an irregular tear permitting free intercommunication between the sac and the aorta. Between this tear and the upper margin of the opening described above was a bridge of firm aortic tissue. The endothelium of the right auricle over the sac was rough and thickened. The wall of the sac was formed of connective tissue and endothelium. It contained only some recent coagula, none that were laminated. The coronary artery arose immediately above the sac but was not involved in it. The leaflets of the aortic valves were perfectly healthy; other valves normal. The endothelium of the heart showed no spots of degeneration except that mentioned in the right auricle. The aorta above the sac, as well as the coronary arteries, was not in the slightest degree atheromatous. Both sides of the heart contained some chicken-fat clots. Lungs deeply congested. Other organs normal.

ANEURISM OF THE AORTA. EMPYEMA.

Presented by W. E. HUGHES.

J. H. W., aged thirty-five years, a shoemaker, was admitted to the University Hospital under the care of Dr. E. T. Bruen, December 26, 1883. He had used alcohol decidedly to excess, but has never been much exposed to weather, and has never done any hard work. There is no history of venereal disease. There is a distinct rheumatic family history, and he himself had had, two years ago, acute articular rheumatism; since then he has had occasional fugitive pains, principally in bad weather. Fifteen months ago he caught cold, and soon after began to feel slight pains along the crest of the left ilium. The pain increased for four days when it had become almost unendurable, and extended from the left loin along the crest of the ilium into the groin. His urine was passed frequently and painlessly in small quantities, and contained no blood. The pain was ameliorated by treatment, but not wholly removed, though there was not enough to keep him from following his usual occupation; it was almost invariably aggravated by damp weather, and was not influenced by motion. Twice since then he has had paroxysms of severe pain, and each time, after taking a mixture containing oil of turpentine, urination has been frequent and painful, and the urine has contained blood. For the last two months he has had more or less stitch like pain at the base of the left chest and a hacking cough. His general health has been failing only slightly. He thinks he has lost about ten pounds of flesh. On admission his face was pinched and anxious, his breathing rapid and shallow, with intense pain at the base of the left lung. Physical examination showed friction sounds at the base of the left lung, with evidences of a small amount of fluid in the left pleural cavity, collected posteriorly. The respiratory murmur over the upper part of the left lung was not quite so distinct as that over the right. The apex beat of the heart was not ascertainable with certainty, but seemed to be a little outside the normal point. The sounds at the apex were indistinct, and synchronously with the systole was a rubbing sound, heard only during inspiration. Toward the base of the heart was developed a harsh systolic murmur, best heard over the upper bone of the sternum, conducted feebly into the carotids, and not heard posteriorly. The heart action was too strong, the whole pericardium heaving. The normal area of cardiac dullness over the upper bone of the sternum was somewhat widened.

He complained of constant dull pain running from the left loin along the crest of the ilium. Urination was normal, and the urine contained no abnormal constituents. Under the use of salicylate of sodium the pleuritic pain was quickly relieved, the lumbar pain completely disappeared after a course of alkaline diuretics. The fluid in the left pleural cavity slowly increased for a while, then remained stationary till one week before his death, when there was a rapid increase. The pleural friction sounds came and went. The friction sounds heard over the heart were even now variable, sometimes systolic, sometimes double, occasionally dependent upon the respiration and again occurring regularly with every beat of the heart. Gradually to the left of the sternum in the second and third interspaces a new centre of pulsation developed apparently distinct from the cardiac impulse, and over this area resonance was impaired. Two months after he was first seen a systolic murmur was detected about the middle of the posterior border of the left scapula distinct from the murmur heard anteriorly. Coincidentally with the development of these conditions there was a steady decrease in the amount of air passing into the left lung. There was no other pressure symptom. For a month before he died he had irregular rises of temperature with profuse perspirations and lost flesh rapidly.

April 22d Dr. Wharton introduced a tube into the

left pleural cavity through which a large amount of sero pus drained off. He died April 27th.

Autopsy, twenty-four hours after death. Body much emaciated. In the sixth interspace one inch anterior to the mid-axillary line is an opening leading directly into the left pleural cavity which is filled forward to the anterior axillary line and upward to the spine of the scapula with a sero-purulent liquid surrounded by walls covered with a pyogenic membrane. The lung occupies the remainder of the pleural cavity and is everywhere closely adherent: it is compressed, the fibrous tissue is increased, and there is slight catarrh of the bronchial mucous membrane. The pericardium is dotted with scattered patches of recent lymph and its cavity contained three ounces of flaky serum. The heart is somewhat enlarged, the valves perfectly normal. The aorta is dilated, its endothelium proliferated, roughened, and in places calcareous. Springing from the arch posterior to the origin of the left carotid and subclavian arteries is an aneurism the size of a filbert extending back into the connective tissue to the left of the trachea. At the end of the descending part of the aorta is another aneurism as large as a peach springing from the right posterior surface of the aorta eroding the anterior face of the bodies of the fifth, sixth, and seventh dorsal vertebræ, pressing toward and almost occluding the left bronchus. It has ulcerated through the wall of the bronchus, but exudation of blood has been prevented by a firm laminated clot which fills this opening. There was no pressure on the œsophagus nor on nerves. At the origin of the cœliac axis is another aneurism half as large pretty well filled with laminated clots. Kidneys and other organs healthy.

Recent Literature.

The Treatment of Backward Displacements of the Uterus and of Prolapsus Uteri by the New Method of Shortening the Round Ligaments. By WILLIAM ALEXANDER, M. D., M. Ch. Q. U. I., F. R. C. S. Eng. London: J. & A. Churchill. 1884.

The title of this book explains its purpose and scope. We confess to having taken it up with a rather strong impression that it would be difficult to commend it, but find, after reading it, that we must modify our preconceived judgment somewhat. The author refers to his ill success in treating many obstinate backward displacements and cases of prolapsus uteri by the routine methods of plastic operations on the vagina and by pessaries, and hence conceived this operation to help him out. It is simple, merely cutting down on the round ligaments before they spread out in the mons veneris, shortening them by traction, and then fastening them in their new position by sutures. The author gives the history of twenty-two cases, in all of which the operation was successful, that is, the uterus was held in its new position, and annoying symptoms were relieved. Other cases treated in the same way by other surgeons have been equally successful.

We were prepared to condemn the operation as unnecessary, and as forcibly illustrating the "*cacoëthes operandi*" which is said to be so characteristic of gynæcologists in general, and a failing of which our English brethren are only too ready to accuse Americans, and after reading what Dr. Alexander has to say we are still of that opinion as regards the majority of his cases. In the first place our experience as to the difficulty of holding the uterus in place by a pessary and the discomfort of the patient while wearing it have been totally different from that of the author. Where the uterus is not bound down by adhesions (and such cases he does not pretend to treat by this method) it is an exceptional occurrence that a suitable pessary cannot be fitted and be well borne. For the rare case where a support cannot be tolerated we can conceive this operation to be of great value.

In cases of prolapsus uteri, however, where, as a rule, there is cystocele and rectocele, consequent upon a ruptured perinæum, we should be afraid that the operation would be only palliative, and that the ligaments would again stretch. In such cases the restoration of the perinæum, or a plastic operation on the anterior wall, or both, it may be, would seem absolutely necessary to prevent a recurrence of the trouble. A sufficient length of time has not elapsed since the first operations to fairly test this point.

The author is enthusiastic, and naturally so, and would be inclined to operate without sufficient trial of more simple methods. He deserves credit, however, for the ingenious operation he has advised, and we think it deserves its place with other methods, to be used in the exceptionally obstinate case which will not yield to other forms of treatment. F. H. D.

The Hip and its Diseases. By V. P. GIBNEY, M. D. Bermingham & Co. 1884.

In stating that Dr. Gibney's work is the most important book that has appeared upon the subject there is little fear that the limits of truth are overstepped, for not only is it a valuable and useful publication, written by one who has familiarized himself with what others have written, who is an accurate and conscientious observer, and who has had for many years unsurpassed opportunities at his hospital clinic for observing this disease and its consequences, but also the subject is one which has not attracted many medical writers of weight. Many books have been written upon the diseases of joints, but the diseases of the hip-joint have been chiefly considered in monographs advocating certain methods of treatment. It is certainly a relief to find something written on the subject in a broad catholic spirit too often wanting in the enthusiast who believes that Rome is to be approached only by one road, and that all other ways lead to the Avernus of unsuccessful surgery.

Dr. Gibney justly insists on the necessity of a clear diagnosis at the outset and not of a guess on the part of the medical attendant that "trouble at the hip" exists. The pathological changes wrought by the disease are clearly stated by Dr. Gibney and well illustrated by clinical and pathological facts, and the matter of diagnosis is well treated. The chapters on treatment are perhaps less satisfactory, chiefly because Dr. Gibney in a desire to be just has been led to describe all the methods in vogue, giving to some perhaps more prominence than they deserve.

A word must be said in regard to the illustrations, for which we imagine the publishers (and not Dr. Gibney) are responsible. If we were in the state of civilization of the North American Indians perhaps some satisfaction might be derived from these blurred woodcuts, as some value is accorded to the carved figures of the Aleuts, but as Americans confessedly lead the world in wood engraving, it is simply an insult to the

medical profession to offer illustrations which indicate either that physicians are decades behind the public in matters of taste or that medical men are intellectual cormorants, and do not care how their mental food is cooked and served provided only the lump of nutrition is given them.

Medical and Surgical Journal.

THURSDAY, JULY 17, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

PUBLIC HEALTH, PUBLIC WEALTH.

WE reproduce in another column extracts from Sir James Paget's eloquent address on the National Value of Public Health, delivered at the inauguration of the juries of the International Health Exhibition and published in the London medical journals of June 21st. Sir James never touches a subject without illuminating it, and there are few speakers or writers whose English is more attractive. It is impossible to read this address without a glow of philanthropic enthusiasm at the thought of the apparently possible realizations in health and wealth if wisdom could only be inculcated. Not the degree of wisdom which may be attainable in the future, but even that which is already in possession, and is crying aloud through public and private organizations that men may hearken. As the address points out, we are in no way more justified in indulging our fancy as to what may be done for national health in the future than by noting what has been done in the immediate past, which is strikingly illustrated by a statement made in a paper before the London Statistical Society, "that if the English death-rate should continue at the low average of the five years 1876–1880, the mean duration of male life in that country would be increased by two years, and that of female life by no less than 3.4 years as compared with the English life table; moreover among males seventy per cent., and among females sixty-five per cent., of this increased life would be lived between the ages of twenty and sixty years, or during the most useful period."

Whatever is possible in England for the amelioration of sickness and suffering and the mitigation of sorrow and waste is in a larger measure possible here in the United States, where there is less of the past to contend with and more of the present to encourage in varied climates and cheap, abundant, and accessible lands for a vastly larger population than we shall have for many years to come. And one potent auxiliary we should be able to count upon in striving for an ideal national health is a widely diffused system of popular education which, where it does more than to make the young discontented with "that station in life unto which it has pleased God to call them," should help them to find out what nature has fitted them to do, and to learn to adapt themselves more readily than the ignorant to the surroundings among which they may find themselves.

In the address the pattern healthy man is described as one who can do his work vigorously wherever and whatever it may be, and a distinctive characteristic of the best health is offered by a union of strength with a comparative indifference to the external conditions of life and a ready self-adjustment to their changes.

"He should not be deemed thoroughly healthy who is made better or worse, more or less fit for work, by every change of weather or of food; nor he who, in order that he may do his work, is bound to exact rules of living. It is good to observe rules, and to many they are absolutely necessary; but it is better to need very few besides those of moderation and cleanliness, and, observing these, to be able and willing to live and work hard in the widest variations of food, air, clothing, and all the other sustenances of life.

"And this, which is a sign of the best personal health, is essential to the best national health. For in a great nation, distributed among its people, there should be powers suited to the greatest possible variety of work. No form or depth of knowledge should be beyond the attainment of some among them; no art should be beyond its reach; it should be excellent in every form of work. And, that its various powers may have free exercise and influence in the world, it must have, besides, distributed among its people, abilities to live healthily wherever work must be or can be done.

"Herein is the essential bond between health and education. I do not know whether health or knowledge contributes most to the prosperity of a nation; but no nation can prosper which does not equally promote both; they should be deemed twin forces, for either of them without the other has only half the power for good that it should have."

This ideal of the healthy man as one equally and proportionally developed in all directions, and not as being overdeveloped in some direction at the expense of other parts of the system, is to be carefully kept in sight, that mere muscular hypertrophy be not regarded as strength nor nervous excitability as mental ability.

Thus far we may yield ourselves to the contagious enthusiasm inspired by an eloquent portrayal of the legitimate results of preventive medicine and of the cultivation of self control. But we must not forget that many years and lives were spent in the fruitless search for the philosopher's stone and the fountain of youth, and the present epidemic of cholera extending and developing itself in France, with its attendant unreasoning panics, shows only too clearly how far the civilized world is from the position which existing knowledge demands that it should occupy.

Perhaps the demonstration of the weak spots in the world's armor against disease will lead all the quicker to the wished-for result.

SPAYING COWS AND PURE MILK.

THE question of securing pure milk at a moderate price is at once so important and so difficult a one, especially in large cities, that any suggestions offering a reasonable probability for simplifying it are likely to attract attention and enforce consideration in proportion to their merits.

A paper read last winter by Mr. L. F. Abbott before a Section of the Suffolk District Medical Society, in Boston, and published in this JOURNAL, page 317, on The Milk Supply of Boston, and the Benefit to be Derived from Spaying Cows, has evidently attracted a good many readers who have been struck with the writer's account of his own experience, and with the conclusions which he draws.

As a rule due credit is given Mr. Abbott for his experiments, though a recent article on Ovariotomy in Cows, in a London medical contemporary, scarcely alludes to the source whence such information as is therein given was evidently taken. Mr. Abbott not being a medical man we are none the less desirous that he should be accorded such recognition as his zeal and intelligence in this matter merit, whether the spaying of cows shall or shall not eventually prove a solution to some extent of the milk problem.

We are glad that the article in question has attracted attention in England as well as in this country, for the problem of milk supply is certainly no nearer a satisfactory solution in London than in New York or Boston, and we may hope to receive material aid from the efforts of our professional brethren there who are earnestly laboring in the same direction. The forthcoming report of a committee appointed at the same meeting before which the paper above alluded to was read will shortly be made public. This committee has been holding meetings for some months past, and has handed in a preliminary report to be followed later by further communications on the same subject. The work of the committee has been arduous, and its investigations have extended over the eastern portion of the State of Massachusetts. It is hoped that the final report and recommendations may have the effect, in connection with a more thorough system of inspection and analysis, of improving the quality of the milk supplied to the towns of that State, beginning with Boston.

OUR BOARDS OF HEALTH AND THE STATE DEPARTMENT ON CHOLERA.

BY way of precaution against the introduction and spread of cholera the State Board of Health of New York has issued a long memorandum, a copy of which has been sent to every local Health Board in the State. The history of former invasions of the disease warrants the belief that its reappearance here is probable, and some account is given of the outbreaks that occurred in this country in 1865, 1866, 1867, and 1873. In every country where the contagium exists it has ceased to be repropagated beyond the sanitary lines which separate the cleansed, drained, and ventilated premises and well-conditioned inhabitants from the filthy, or where polluted food and water and harmful beverages prepare the system for the fatal operation of the poison. For cholera to be diffused from continent to continent it must have as factors for its cultivation a centre of pollution for its cradle, a ship for its transport, and a number of towns prepared for its reception and development. Now, before the exotic infection has come, it is advised — as was urged in our editorial of July 3d — that all local Boards of Health and all householders should lose no time in enforcing such thorough scavenging and cleansing, such cleaning of sewers, drains, and ditches, and such ventilating, drying, lime-washing, and disinfecting of cellars and all damp and unclean places that if cholera comes its infective germs shall find no soil or foul surface in which to propagate epidemically. After describing the manner of the development and spread of the contagion the memorandum of the New York Board concludes by urging more specifically the duty of taking such sanitary precautions as will prevent such a tendency.

The brunt of the work of guarding against an entrance of cholera must naturally devolve upon the boards of health of our Atlantic States and sea-board cities, but the inland States have learned from the last European epidemic of small-pox that home precautions are far from superfluous. The Illinois Board with its customary energy has issued through its secretary, Dr. Rauch, a circular which has been sent to the mayors or presidents of village boards of 644 cities, villages, and towns throughout that State. From this sensible circular we make the following extracts, which are also entirely consonant with our editorial of July 3d, whose warning was, as subsequent events show, not premature: —

"It is entirely possible that we may escape a visitation of Asiatic cholera this year, although there is yet plenty of time for the disease to reach our shores before cold weather. But even if there were no danger from this source, it should be remembered that everything which is done in the direction of sanitary improvement benefits the general health, reduces the amount of sickness, and lessens the death-rate. An obvious duty, therefore, rests at all times, but more urgently at present, upon those charged with the administration of public health affairs, to take such steps as may be necessary to remedy any defects in the existing sanitary status.

"To this end a general inspection of the entire territory under your jurisdiction should be made forthwith, and all nuisances or other conditions injurious to the public health which may be disclosed by such inspection should be promptly abated. Especial attention should be paid to, First, The condition of the water supply. Second, The disposition of night-soil, garbage, and sewage. Third, The cleansing of streets, alleys, and other public places. Fourth, The supervision of food supplies, and of market-places, slaughter-houses, and similar establishments. Fifth, The general sanitation of every house and its surroundings.

. . . . . .

"It is desired that this work of inspection and remedying of evils and defects be begun at the earliest practicable moment, and a preliminary report be made to this office covering, in a general way, the existing sanitary condition, and the measures adopted and enforced for its improvement."

Secretary Frelinghuysen has, by cable, instructed the consular officers at London, Liverpool, Marseilles, Havre, Bordeaux, Bremen, and Hamburg to at once appoint competent physicians to inspect all vessels and passengers departing for the United States from those ports. The consuls are instructed to refuse clean bills of health in all cases except upon the recommendation of the sanitary inspector that such bills be given; and to report by cable any case of infectious or contagious disease known to exist on board of a vessel at the time of her departure for the United States. This course is adopted in order that the health officers in our ports may have timely warning of approaching danger, and be prepared to take such measures as shall prevent the scourge from gaining a foot-hold in this country, and is one in support of which international coöperation was sought by the abortive Congress called at Washington in January, 1881.

MEDICAL NOTES.

— His Excellency the Governor of this Commonwealth makes his visits upon the State institutions unexpected and unannounced. On a recent visit to the Danvers Lunatic Hospital he walked in at a rear gate communicating with the servants' quarters early in the morning and had made a pretty extensive investigation before he met the head official of the institution. We believe that an inspection of Tewksbury was made in the same simple fashion, and though no time was given for shuffling tanned human skins and other unpleasant objects out of sight, yet the condition of things there as well as at Danvers met with approval. The good Haroun Al Raschid found he could learn what was going on in his dominion fully as well when he went about in the dress of a citizen as in his official state, and investigating committees and governors sometimes do well to follow his example.

— The approach of the hay fever season suggests mention of some of the remedies which have recently been claimed as moderately successful. Dr. W. T. Phillips recommends belladonna, which he found successful last year (*British Medical Journal*, July 14, 1883). In the same journal (June 7th, page 1090) he now gives the dose as one and a quarter minim of the succus every hour till relieved (thirty minims to three ounces of water). For coryza, Dr. G. E. Dobson recommends (*Lancet*, May 31st, page 978) the inhalation of the vapor of camphor and steam, the vapor being made to come in contact with the outer surface of the face surrounding the nose by means of a paper cone placed with the narrow end downwards in a vessel containing hot water and a drachm of coarsely powdered or shredded camphor. If this is continued ten or twenty minutes at a time, and repeated three or four times in as many hours, a cure is usually effected.

— The *London Medical Record* quotes from the *Russkaia Meditz* Dr. Prokop Popoff as stating that in more than three hundred cases of acute and chronic rheumatic coryza he used, with great success, the following simple plan of treatment: Twice daily (in the morning on rising, and at night on going to bed) for two days the patients are ordered to wash their legs from the sole up to the knee with ice-cold water, and to subsequently rub the washed parts with a dry towel or a piece of rough linen or cloth until a vivid redness and feeling of warmth appears. The whole procedure takes not more than five minutes. No other measures or precautions are required. A striking improvement follows already on the next day; in fact, the improvement is usually so great that many patients content themselves only with one day's treatment, regarding themselves as cured.

— We learn from one of our English exchanges that one of the latest additions to the Health Exhibition is an anthropometrical laboratory, which has been organized by Mr. Francis Galton, and has been fitted with a set of instruments for the measurement of certain personal facts. A small fee will be charged for admission, and in return for this the visitors will be furnished with a pamphlet, explanatory of the objects of anthropometry, and a carefully filled-up schedule, of which a duplicate will be kept for statistical purposes. This record will contain name (or initials) age, sex, profession, color of hair and eyes, place of birth and residence, height (standing and sitting), weight, chest capacity, as measured by a spirometer, strength of squeeze and pulse, swiftness of blow, acuity of sight and hearing, and the conditions of the color sense.

NEW YORK.

— In a case of death from the eating of raw ham, which occurred recently at Arietta, in Hamilton County, and which has been investigated by a committee of the State Board of Health, the muscular tissue of the patient has been found to be swarming with trichinæ.

— Dr. Cyrus Edson, chief of the second sanitary division, has presented to the New York Board of Health a report embodying the results of analyses made by Dr. Elwyn Waller of the water from nine artesian wells in the city, which, with one exception, are used by manufacturers of soda and mineral waters, and which vary in depth from thirty to one hundred and sixty-nine feet. The water taken from seven of these wells is pronounced bad and unwholesome, and from two others is characterized as doubtful. The report continues: "Owing to the geological formation of the island the water in many of the wells, however deep, is the drainage of the district closely adjacent to where the well is sunk. The importance of compelling the manufacturers to use pure and wholesome water is manifest when it is remembered how frequently mineral and carbonated waters are prescribed by physicians for invalids and persons in delicate health who are most liable to contract disease.

— State Comptroller Chapin has appointed Prof.

Charles S. Sargent, of Harvard, upon the committee to investigate and report upon the system of forest preservation in the Adirondacks.

Miscellany.

THE NATIONAL VALUE OF PUBLIC HEALTH.

SIR JAMES PAGET, in his address delivered at the inauguration of the juries of the International Health Exhibition, presented in a striking manner some of the losses arising from ill health, apart from and in addition to the cases of death. We make room for the following extracts: —

"I think, then, that we cannot escape from the reasons to believe that we lose in England and Wales, every year, in consequence of sickness, 20,000,000 of weeks' work; or, say, as much work as 20,000,000 of healthy people would do in a week.

"The number is not easily grasped by the mind. It is equal to about one fortieth part of the work done in each year by the whole population between fifteen and sixty-five years old. Or, try to think of it in money. Rather more than half of it is lost by those whom the Registrar-General names the domestic, the agricultural, and the industrial classes. These are rather more than seven millions and a half in number, and they lose about 11,000,000 of weeks; say, for easy reckoning, at a pound a week; and here is a loss of £11,000,000 sterling from what should be the annual wealth of the country. For the other classes, who are estimated as losing the other 9,000,000 weeks' work, it would be hard and unfair to make a guess in any known coin; for these include our great merchants, our judges and lawyers and medical men, our statesmen and chief legislators; they include our poets and writers of all kinds, musicians, painters, and philosophers; and our princes, who certainly do more for the wealth and welfare of the country than can be told in money. . . .

"Take, for example, such a disease as typhoid fever — that which Mr. Huxley has rightly called the scourge and the disgrace of our country. It has of late destroyed in England and Wales, among persons in the working time of life, nearly 4000 in the year. Its mortality is about fifteen per cent.; so that if, in any year, 4000 die of it, about 23,000 recover from it. Of these the average length of illness is, on the authority of Dr. Broadbent, about ten weeks. Here, therefore, from one disease alone, and that preventable, we have an annual loss of 230,000 weeks' work, without reckoning what is lost with those who die. And the same may be said of nearly all the diseases that are most prominent in the bills of mortality. The record of deaths, sad as it is, tells but a small part of the losses of happiness and welfare that are due to sickness. It is as if, in a great war, we should have a regular return of the numbers killed, but none of the numbers wounded, though these, more than the killed, may determine the issue of the war. . . .

"But, some may ask, can these things be prevented? Are they not inevitable consequences of the manner of life in which we choose or are compelled to live? No; certainly they are not. No one who lives among the sick can doubt that a very large proportion of the sickness and the loss of work which he sees might have been prevented; or can doubt that, in every succeeding generation, a larger proportion still may be averted, if only men will strive that it may be so.

"Let me enumerate some of the chief sources of the waste, as they appear to one's self in practice.

"Of the infectious fevers, small-pox might be rendered nearly harmless by complete and careful vaccination. Typhus and typhoid, scarlet fever and measles, might, with proper guards against infection, be confined within very narrow limits. So, probably, might whooping-cough and diphtheria.

"Of the special diseases of artisans there are very few of which the causes might not be almost wholly set aside. Of the accidents to which they are especially liable the greater part, by far, are due to carelessness.

"Of the diseases due to bad food and mere filth; to intemperance; to immorality; in so far as these are self-induced, they might, by self-control and virtue, be excluded. And with these scrofula, rickets, scurvy, and all the wide-spread defects related to them, might be greatly diminished.

"It can only be a guess — but I am sure it is not a reckless one — if I say, that of all the losses of work of which I have spoken, of all the millions of weeks sadly spent and sadly wasted, a fourth part might have been saved, and that henceforth, if people will have it so, a still larger proportion may be saved. . . .

"We may become the more sure of what may be done by looking at what has been done already. Let me show some of it; it will be a relief to see something of the brighter side of this picture.

"In a remarkable paper lately read before the Statistical Society Dr. Longstaff says: 'One of the most striking facts of the day, from the statistician's point of view, is the remarkably low death-rate that has prevailed in this country during the last eight years.' In these years the annual death-rate has been less than in the previous eight years in the proportion of two deaths to every 1000 persons living. The average number of deaths has been 50,000 less in the last than in the previous eight years. Doubtless many things have contributed to this grand result, and it is not possible to say how much is due to each of them; but it would be unreasonable to doubt that the chief good influence has been in all the improved means for the care of health which recent years have produced. This is made nearly certain by the fact that the largest gains of life have been in the diminution of the deaths from fever, and of the deaths in children under fifteen years old, for these are the very classes on which good sanitary measures would have most influence.

"The annual number of deaths from typhus, typhoid, and the unnamed fevers has been about 11,000 less than it was about twenty years ago. The annual number of deaths of children under five years old has been about 22,000 less than it was; and that of children between five and fifteen has been upwards of 8000 less.

"These are large results, and though they tell of only deaths, yet they bear on the chief subject I have brought before you, — the working power of the nation: for, however much we might assign to improved methods of medical treatment of fever, yet the diminished number of deaths means a very large diminution in the total number of cases. The deaths during the working years of life were 6500 less; and, this being so, we may hold that, if the average mortality was say, twenty-five per cent., the diminution in the total number of cases must have been at least 25,000; and if we may believe, as before, that each of these involved ten

weeks of sickness, we have, in these fevers alone, a clear saving of 185,000 weeks' work in every year. . . .

"It is said, whether as fact or fable, that the pursuit of science and of all the higher learning followed on the first exercise of the humanity which spared the lives of sick and weakly children; for that these children being allowed to live, though unfit for war or self-maintenance, became thinkers and inventors. But science and art are not dependent upon invalids; minds are not the more free or the better now for having to work in feeble bodies; each nation needs for its full international influence both health and knowledge, and such various and variable health, that there should be few places on earth or water in which some of its people cannot live, and multiply, and be prosperous.

"If, therefore, we or any other people are to continue ambitious for the extension of that higher mental power of which we boast, or for the success of the bold spirit of enterprise with which we seek to replenish the earth and subdue it; if we desire that the lessons of Christianity and of true civilization should be spread over the world, we must strive for an abundance of this national health, tough, pliant, and elastic, ready and fit for any good work anywhere."

CHOLERA AND SANITARY NEGLECT AT TOULON.

THE outbreak of cholera at Toulon, says *The Lancet*, will surprise no one who is at all acquainted with the barbaric condition, so far as sanitation is concerned, of this, the French Portsmouth. When the cholera last visited France this town suffered most severely, but the warning was of no avail. It is said, on credible authority, that the death register if examined will reveal a surprising number of fatal cases of typhoid fever among strangers visiting the town, while among the native population this fever is of comparatively rare occurrence. The latter, it is maintained, must be inoculated by the foul atmosphere if it fails to kill during infancy; but friends and visitors coming from more wholesome districts at once fall victims to this fever if they are imprudent enough to remain a little while at Toulon. Military experience confirms this theory. So long ago as March 26, 1881, it was reported that Dr. Galliott, of the Marines, had received a gold medal from the French Government for an essay on typhoid fever at Toulon. The facts revealed, however, were of so alarming a nature that the Government absolutely refused to communicate to any one the contents of this report; and, while awarding the gold medal to Dr. Galliott, enjoined upon him the strictest secrecy. In spite of this injunction, the main points were ascertained, from which it appeared that at the barracks of the Mourillon, holding some two thousand soldiers, about a thousand cases of illness had occurred in the course of twelve months. Of these half were fully developed cases of typhoid fever, while the others, though more doubtful, were also for the most part clearly attributable to bad hygiene. The volunteers for one year's service, being younger men, were the principal victims; and, with the soldiers as with the civil population, those who had come from distant and healthy districts were the chief sufferers, while the natives of Toulon escaped. Now, the barracks of the Mourillon are only inhabited by old and inured soldiers; the younger men are sent to the fortresses on the surrounding mountains and islands. Still nothing has been done to improve the general sanitary condition of the town. The public has a just cause of complaint, for the authorities, having suppressed information, have rendered themselves alone responsible. In their own interests they should have taken measures in time, instead of allowing Toulon to become a menace to the health of Europe.

THE RELATION BETWEEN SCARLATINA AND DIPHTHERIA.

THE *British Medical Journal* (April 12th) remarks editorially: —

"The evidence of close relationship in origin and pathology of these diseases is rapidly accumulating. In some cases, barring mistakes in diagnosis, it seems that one develops from exposure to the other. In a recent epidemic at Sutton in-Ashfield they existed side by side. Some of the cases affected had a red eruption, followed by a desquamation of the skin and renal dropsy; others had no rash, but were followed by paralysis. Two cases of what appeared to be scarlatina occurred in an isolated group of cottages; from these contagion was carried to another family, and two children died, one of 'scarlatina maligna,' one of 'diphtheria.'

"In some cases the first patient in a family attacked had vomiting, sudden accession of fever, and a red rash; while others, a week or two later, had no rash, but white patches in the throat, and, in one or two instances, subsequent paralysis of the pharyngeal muscles. One case, beginning apparently as diphtheria, with white patches in the throat, developed on the third or fourth day the scarlatinal rash, which was followed by anasarca, from which he died. In another family, on the other hand, four members had typical scarlet fever in November; in January one of these, and one who escaped, had typical diphtheria.

"At Whitstable and Dunmow, after diphtheria had been prevailing three months, scarlatina appeared. After existing together for a time diphtheria subsided, while scarlatina became more prevalent and more fatal. After five or six months this diminished, and diphtheria again made its appearance. The diagnosis between the diseases was very often impossible.

"The most striking instance mentioned by the writer of the connection between the diseases is the following: A child who had contracted scarlet fever at service came to her home, — one of two isolated cottages. She was convalescent, and pains had been taken to disinfect her clothing and her person. Eight days later her sister was taken ill, and died in two days of 'malignant sore throat.' On the following day three more were attacked with the same disease; one died in two, one in three, and one in ten days. In the last case there was a petechial eruption. It was called 'diphtheria.' The physician in attendance considered the other cases as belonging to this category. A child in the adjoining cottage was taken, ten days after the return of the girl above mentioned, with a sore throat, developed a well-marked scarlet-fever rash on the sixth day, which was followed by desquamation on chest, arms, and legs. Four other children in this family escaped, but a woman who lived some distance away, who came to nurse the children, took diphtheria, and died on the fourth day, while sitting in her chair. The conclusion reached is, that though scarlatina generally originates from personal contagion, and though typical

diphtheria often has a purely local origin, especially from sewer emanations, both diseases are due to an infection which in all cases attacks the throat, from which it is mainly propagated. In passing from person to person it may be so modified as to cause in one instance characteristic scarlatina, in another typical diphtheria, in a third a mongrel affection which it is difficult to refer to either, or to identify by any other name than that of a bad sore throat, and which is, in fact, a connecting link between the two diseases."

REPORTED MORTALITY FOR THE WEEK ENDING JULY 5, 1884.

Deaths reported 3168 (no reports from St. Louis, Cincinnati, Buffalo, and Milwaukee): under five years of age, 1777; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 1107, diarrhœal diseases 796, consumption 325, lung diseases 182, diphtheria and croup 76, measles 61, scarlet fever 44, whooping-cough 31, malarial fevers 29, cerebro-spinal meningitis 26, typhoid fever 24, small-pox nine, erysipelas eight, puerperal fever three. From *scarlet fever*, New York 13, Philadelphia eight, Brooklyn six, Chicago five, Boston three, District of Columbia, Pittsburg, and Providence two each, Lowell, Newton, and Westborough one each. From *whooping-cough*, New York 12, Chicago five, New Orleans three, Philadelphia, Brooklyn, Boston, and District of Columbia two each, Pittsburg, Somerville, and Hyde Park one each. From *malarial fevers*, New York and New Orleans nine each, Brooklyn seven, Chicago two, Philadelphia and Nashville one each. From *cerebro-spinal meningitis*, Philadelphia 10, New York and Fall River three each, Charleston and Worcester two each, Chicago, Lowell, Lawrence, Holyoke, Taunton, and Newton one each. From *typhoid fever*, Philadelphia eight, Chicago four, Baltimore three, New York and Boston two each, New Orleans, Nashville, Cambridge, and Marblehead one each. From *small-pox*, New Orleans eight, Philadelphia one. From *erysipelas*, New York and Chicago two each, Philadelphia, Brooklyn, Baltimore, and New Bedford one each. From *puerperal fever*, Philadelphia, Brooklyn, and Baltimore one each.

In 103 cities and towns of Massachusetts, with an estimated population of 1,388,574 (estimated population of the State 1,955,104), the total death-rate for the week was 15.35 against 15.41 and 15.00 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending June 21st, the death-rate was 18.7. Deaths reported 3133: acute diseases of the respiratory organs (London) 227, measles 148, whooping-cough 116, diarrhœa 55, small-pox (London 41, Liverpool 11, Sheffield four, Cardiff, Sunderland, Hull, and Manchester one each) 60, fever 38, diphtheria 11. The death-rates ranged from 11.3 in Derby to 26.6 in Liverpool; Birmingham 17.2; Blackburn 20.8; Bradford 19.7; Leeds 20.1; Leicester 15.7; London 17.8; Manchester 23.4; Nottingham 15.8; Sheffield 17.9. In Edinburgh 19.7; Glasgow 24.6; Dublin 27.1.

The meteorological record for the week ending July 5th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the U. S. Signal Corps: —

Date. June–July, 1884.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE, APRIL 1, 1884, TO JUNE 30, 1884.

BAILHACHE, P. H., surgeon. Detailed as chairman of Board to examine candidate for appointment into the Revenue Marine Service. May 17, 1884.

VANSANT, JOHN, surgeon. To proceed to Empire City, Oreg., as inspector. April 2, 1884.

HUTTON, W. H. H., surgeon. Granted leave of absence for twenty-five days. May 14 and June 9, 1884.

MILLER, T. W., surgeon. Granted leave of absence to attend the meeting of the American Medical Association. May 1, 1884.

To proceed to Pittsburg, Penn., Ashtabula, Ohio, Buffalo, N. Y., and Detroit, Mich., as inspector. May 10, 1884.

WYMAN, WALTER, surgeon. To proceed to Crisfield, Md., as inspector. April 11, 1884.

Detailed to represent the Marine Hospital Service as delegate to the American Medical Association. April 17, 1884.

Detailed as president of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service. May 20, 1884.

To examine cadet-graduates Revenue Marine Service as to physical qualifications. May 31, 1884.

Detailed as member of Commission to inspect United States buildings at quarantine station on the Delaware River. June 16, 1884.

AUSTIN, H. W., surgeon. Granted leave of absence to attend the meeting of the American Medical Association. May 2, 1884.

GASSAWAY, J. M., surgeon. When relieved by Passed Assistant Surgeon Mead to proceed to Portland, Maine, and assume charge of the service. April 16, 1884.

Granted leave of absence for thirty days. May 28, 1884.

STONER, G. W., passed assistant surgeon. When relieved by Surgeon Gassaway to proceed to Cairo, Ill., and assume charge of the service. April 16, 1884.

When relieved by Surgeon Gassaway to report in person to the surgeon-general. June 20, 1884.

IRWIN, FAIRFAX, passed assistant surgeon. Granted leave of absence for twenty-one days. June 19, 1884.

MEAD, F. W., passed assistant surgeon. When relieved by Assistant Surgeon Devan to proceed to Philadelphia, Penn., and assume charge of the service. April 16, 1884.

Detailed as recorder of Board for physical examination of candidates for appointment as cadets in the Revenue Marine Service. May 20, 1884.

CARTER, H. R., passed assistant surgeon. To inspect unserviceable property at the San Francisco Hospital. May 24, 1884.

WHEELER, W. A., passed assistant surgeon. To inspect unserviceable property at the Chicago Hospital. May 24, 1884.

BENSON, J. A., passed assistant surgeon. Granted leave of absence for thirty days. April 14, 1884.

When relieved by Passed Assistant Surgeon Stoner to report to him for temporary duty. May 19, 1884.

BANKS, C. E., passed assistant surgeon. Detailed as member of Board to examine physically candidate for appointment into the Revenue Marine Service. May 17, 1884.

To inspect unserviceable property at Baltimore, Md., New York, N. Y., and Boston, Mass. May 26 and June 2, 1884.

BENNETT, P. H., assistant surgeon. Granted leave of absence for twenty days. June 28, 1884.

DEVAN, S. C., assistant surgeon. To proceed to Port Townsend, W. T., relieve Passed Assistant Surgeon Mead, and assume charge of the service. April 14, 1884.

URQUHART, F. M., assistant surgeon. Granted leave of absence for thirty days. May 22, 1884.

YEMANS, H. W., assistant surgeon. To report to Captain M. A. Healey for duty as medical officer during cruise of revenue cutter Corwin. April 16, 1884.

GLENNAN, A. H., assistant surgeon. To proceed to Mobile, Ala., for temporary duty during sickness of Passed Assistant Surgeon Goldsborough. June 17, 1884.

APPOINTMENT.

BROOKS, STEPHEN D., M. D., of Massachusetts, having passed the examination required by the Regulations, was appointed an assistant surgeon by the Secretary of the Treasury, May 15, 1884.

(Dr. Brooks had previously served as an acting assistant surgeon from March, 1883, to May, 1884.)

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JULY 4, 1884, TO JULY 11, 1884.

BIRMINGHAM, H. P., first lieutenant and assistant surgeon. From Fort Bayard, N. M., to Fort Bliss, Texas. Paragraph 3, S. O. 137, headquarters Department of Missouri, July 3, 1884.

PROMOTIONS TO DATE FROM JULY 2, 1884.

PERIN, GLOVER, to be assistant surgeon-general, with rank of colonel.

SMITH, ANDREW K., to be surgeon, with rank of lieutenant-colonel.

MIDDLETON, PASSMORE, to be surgeon, with rank of major.

PROMOTIONS.

To be assistant surgeons with the rank of captain, after five years' service, in accordance with the Act of Congress of June 23, 1874: —

KANE, JOHN J., assistant surgeon, June 3, 1884.
BANISTER, JOHN M., assistant surgeon, June 3, 1884.
APPEL, AARON H., assistant surgeon, June 3, 1884.
RICKARD, CHARLES, assistant surgeon, June 3, 1884.
CARTER, W. FITZHUGH, assistant surgeon, June 3, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE WEEK ENDING JULY 12, 1884.

LUMSDEN, G. P., passed assistant surgeon. Ordered to U. S. S. Wyandotte.

PERSONS, R. C., passed assistant surgeon. Detached from the Wyandotte and placed on waiting orders.

Address.

THE PHYSICIAN A POPULAR EDUCATOR.[1]

THE ANNUAL DISCOURSE BEFORE THE MASSACHUSETTS MEDICAL SOCIETY, JUNE 11, 1884.

BY JOHN CROWELL, M. D., OF HAVERHILL.

SAID Hippocrates, two thousand years ago, "a dry soil is essential to health." Yet Professor Chandler declares that not one house in a hundred in New York has a properly constructed cellar, which, he contends, explains the large proportion of deaths from consumption, and the prevalence of rheumatism in that metropolis. Sewer connections are usually made with tile drains, which are rarely tight, and hence they seriously pollute the soil. These cellars are crowded with all kinds of domestic rubbish, and often we find open water-closets for the servants in close proximity to the air box which feeds the heating apparatus. How many refrigerators have their drip-pipes connected directly with the house-drain! How often are cisterns and water-tanks exposed to like pollution! How often are the spaces behind the wood-work of basins, sinks, and other fixtures foul with dampness, mould, and the accumulation of filth! All the leading cities of the country are guilty of the grossest neglect in the simplest details of domestic drainage and sanitary appliance. We hear the same reports from Brooklyn, Philadelphia, Chicago, and San Francisco.

In our own metropolis of Boston these defects are painfully apparent. Recent reports assure us that many fine residences in the Back Bay region are deficient in sanitary safeguards. Hundreds of houses are built upon piles in made ground. In the process of settling, which may continue for years, the drains become dislocated, and this permits sewage to saturate the foundation and sub-soil. "I have known," writes a standard authority,[2] "seventy-eight cart-loads of earth polluted in this way to be taken from under a building in the city of Boston." Official reports tell us that of three hundred and fifty-one houses examined in Boston in 1878 fifty-five per cent. of the drains were imperfect.

In Chicago, out of seventy-five houses where diphtheria occurred, only four were found in a sanitary condition; and in St. Louis, Health Officer Moore reported, in 1879, that there was probably not a single house with perfect drainage, while in a vast majority every sanitary rule was violated.

Not long since a successful business man invited his family physician to visit and inspect his new dwelling-house built on the outskirts of a suburban city. The house was a "Queen Anne cottage," of the most approved pattern, picturesque in quaint gables and odd porches, and rich in the glow of color from tinted wall and painted glass. The hand of the artist was everywhere apparent, and each adornment suggested a home of refinement and taste. After admiring all these elements of beauty, the medical friend was practical enough to inquire as to the disposal of sewage and the appliances for ventilation and heating. The owner of this "gem of a cottage" was quite oblivious on these points. They had been left to the plumber and the mason, with no personal or official oversight. It was found, upon examination, that the house sewage flowed directly into a cess-pool situated in close vicinity to the house, and unprotected by any trap. The water-closets were supplied by pipes coming from the cistern containing the water used for culinary purposes, and the cellar was damp from the defective drainage of the clay bottom; and neither bath-room nor water-closet had any adequate means of ventilation. The satisfied owner was appalled when told that his beautiful home contained the germs of disease and death, and the good physician only regretted that his unwelcome detection had not been more timely.

How invaluable may be the suggestions and advice of the members of this Society in the location and the construction of dwellings, school-houses, and factories. In a large factory in a neighboring city in this State the water-closets furnished for the operatives on each floor were unprotected by traps, and, as there was no official inspection of the building, the fact was unknown to the owner of the establishment until an epidemic among the operatives directed the attention of the resident physicians to the sanitary condition of the premises.

Since the passage of the Act of 1877, authorizing the establishment of local Boards of Health in the larger towns of the Commonwealth, there has been a marked improvement in those localities that have availed themselves of the wise provisions of the statute. And physicians have rendered a noble work of self-sacrifice in organizing such boards and consenting to remain in official position until a good working system could be secured.

But many of our communities have not yet established such boards, and the smaller towns cannot have the advantages of a complete organization. It is here that the physician can render most efficient work by personal instruction to his neighbors in feasible methods of water supply, in local drainage, in household cleanliness, and in those minor sanitary details which pertain to the order and the decencies of life.

To what kind of places do we send our patients in the summer months for the tonic influences of the blessed air from mountain or sea? Are we careful to inspect the premises and acquaint ourselves with the sanitary conditions of these resorts? How often are they deficient in the simplest rules of cleanliness, with privy, pig-sty, and well in convenient proximity to each other, while frequently, especially in the farm-houses, the dark and unventilated cellars are reeking with the odors of decaying cabbage leaves and musty cider barrels. At a favorite sea-side resort, last summer, typhoid fever made its appearance in one of the "cottages," when it was found that the victims had been drinking water from a well percolated and poisoned by sewage from a defective drain-pipe.

Typhoid dysentery often appears at the old farm-houses to which we send invalids, and we find too late the stagnant pools of sink water and the damp and filthy cellar. These vicious conditions will be remedied when we lift up the warning voice and declare that no patronage shall be given to any resort, however popular, that does not comply with the wholesome and simple rules of sanitary science.

Is the question, "What do we eat," too trivial to arrest the attention of the physician? The people of New England are far behind the rest of the civilized world in the practical accomplishments of the culinary

[1] Continued from page 50.

[2] Charles F. Wingate. Unsanitary Houses of the Rich, North American Review, August, 1883.

art. In the bustle and hurry of our busy population but little attention has been given to the sanitary conditions of cooking, and there is much of truth in the assertion that a French cook will make a nutritious dinner from the remnants of food that we consign to the waste barrel. How rarely do we find good bread, even in families where there is abundance of provisions. How fondly do we cling to the conventional pie and doughnut, as if they were chief among the inalienable rights inherited from the fathers. We smile at the astonished Frenchman who exclaimed, "What a people, a hundred religions and only one gravy!" And yet is there not a sound philosophical principle involved in this ejaculation so far as the gravy is concerned? Most of our methods of cooking seem contrived to destroy rather than to conserve the nutritious elements of the animal fibre, the albumen, the gelatine, and the fibrine. We have much to learn, not only from the French, but also from the Scandinavians, as to the methods of preparing food that shall be palatable, nutritious, and easily digestible.

When that intelligent observer, M. Taine, was visiting England, and inquiring into the methods of domestic life, he asked his host, "How do you cook vegetables in England?" "Cook them!" was the astonished reply, "why we *boil* them, how else *should* we cook them?"

In this connection there is an important class of the community demanding our attention. I refer to the laborers and operatives in our large towns, who labor on the public works and in the factories. Many of these hard-working people are in the habit of "carrying their dinner," which is of course eaten cold, and the contents of these little tin pails and baskets are richer in their variety than in nutrition. No wonder that we have been called a race of dyspeptics. He will be a benefactor to his generation, as well as "put money in his purse," who will devise a simple method of soup distribution among the operatives who depend upon this cheerless method of dining. With large tin cans, transported on hand-carts, hot soup could easily be distributed by dexterous hands among the shops and factories, and for a few cents a comforting and sustaining meal could thus be furnished.

How often do we trace the sallow, attenuated look, the languid eye, and the feeble, inelastic step of many who seek our advice to the lack of proper food at the proper time! How frequently are we obliged to attribute the complicated train of female diseases to the miserable methods of living in cheap boarding-houses, combined with the constant demands of manual labor!

We need more of chemistry as applied to cooking. The public must be instructed in simple methods of preparing food, so that the nutritious elements will be retained; and what better service can the practical chemist render than to prepare a convenient hand-book for popular use containing plain directions upon this vital subject? The philanthropist would substantially advance such benevolent work by offering a prize for the best treatise on practical cooking for general distribution among cooks of every grade, from the elaborate culinary establishments of the homes of wealth, from the fashionable saloon, hotel, and eating-house, down to the humble kitchen of the frugal housewife.

What kind of places do many of our business men occupy as offices, where they make the money spent in the elegant houses where dwell the pets and the idols of home? Too often these counting houses and offices are found in dark, narrow streets, and located in a basement, full of the stifling odors from ill-ventilated warerooms and cellars. Here are found clerks working by gas-light in mid-day, and the result is seen in the sunken eye and the sallow look and the shrunken muscle. Many such places exist in this goodly city, and the laws of mercy cry out for the protection of those who are forced to occupy them.

In the *Conduct of the Sick Room* the services of the physician as teacher are of the first importance. It is here where ignorance will reign supremely, and with fatal sway, unless the firm and intelligent hand of authority interferes in behalf of the helpless and patient sufferers. In the furnishing of the room, in the disposition of air and sunlight and artificial heat; in matters of cleanliness in the clothing and in the necessary appurtenances, and above all in the *nursing*, the vigilant eye and the guiding genius of the medical attendant are among the essential elements in the successful treatment of disease.

In private practice as well as in hospitals the physician should seek to have the furnishing of the sick room very simple, with as little of drapery and heavy carpeting as possible, and he should endeavor to secure ventilation and a proper adjustment of light by such contrivance as his ingenuity can suggest. The popular prejudice against air and sunlight has not yet faded from the face of the earth, and often the attendant will exclude both of these vital elements, as if they were the cause rather than the antidote of disease. In the regulation of artificial heat a good thermometer in the sick room is all important, and its registration should be insisted upon by the physician, and *his* standard of cleanliness in the care of the clothing and the vessels of the room should be often held up as a guide, and, if needful, as a terror, to the presiding genius.

It must be confessed that the average nurse, as found in our country towns and villages, is not the ideal guardian angel of camps and of hospitals, whose fairy shadow, as she flits along the corridors, falls like a benediction upon the helpless sufferers. The country physician has to deal with different material, and oftentimes his greatest embarrassment in the treatment of disease arises from the ignorance or duplicity of the nurse. In the larger towns and cities, and especially in the metropolis, this difficulty has been effectually met and overcome by the training of nurses in the hospitals, and a noble army of helpers is now in the process of this discipline, whose intelligent labors will add to the success of medical treatment wherever they are available.

But in the towns where hospitals do not exist the trained nurse is almost unknown, except in the most highly favored families. This vital want can be effectually met by the physicians of any given locality in the establishment of normal classes for the instruction of all women desiring the office of nurse, the physicians acting as teachers, under a system simple and elastic in its operation. In these classes instruction should be given in those essential duties of the sick room which ought to come within the province of every attendant deserving the name of nurse. The basis of such instruction and its practical working are most admirably and succinctly set forth by Professor Jacobi in

an address delivered a year ago before the Mt. Sinai Training School for Nurses.[1] He says: —

"May I tell you what a good trained nurse may teach, and can teach? How to recognize a fever, how to compare the local temperatures of the several parts of the body, and how to equalize them; she knows that ever so many feeble children might have been saved if but the feet and legs had not been allowed to get cold; how to bathe, when, and when to stop; how to regulate the position of the head, — I remember quite well the case of inflammatory delirium which would always be relieved by propping up the head, — how to treat intelligently an attack of fainting; how to render cow's milk digestible by repeated boiling, or lime-water, or table-salt, or farinaceous admixtures; how to feed in case of diarrhœa; how to refuse food in case of vomiting; how to apply and when to remove cold to the head; how to ventilate a room without draught; and a thousand other things. She will also use her knowledge and influence in weaning the public of nostrums, concerning which hardly anything is known except what you have to pay for the promises of the label. She will break the public of the indiscriminate use of quinia, with its dangers possibly for life; cure you of the tendency of making the diagnosis of malaria the scapegoat of every unfinished or impossible diagnosis; she will teach you that the frequent and reckless domestic use of chlorate of potassium leads to many a case of ailment, to chronic poisoning, possibly in the shape of Bright's disease, or to acute poisoning, with unavoidable death. These are but very few of the things she can do, and but a little of the knowledge she cannot but distribute."

We might add to this enumeration the ability to meet the many emergencies incident to the sick room. How to arrest a post-partum hæmorrhage, how to tie the umbilical cord, how to assist in administering anæsthetics in puerperal convulsions, and, above all, how to prepare the nourishment ordered by the physician.

Ask the ordinary nurse how she makes that popular decoction known as beef tea, or how she prepares the artificial food that many infants are doomed to feed upon, and we shall find a lack of method and uniformity almost ludicrous. Here is where the training hand of the physician should be felt, and by actual object-teaching should he give the necessary instruction.

In those families where the limitations of poverty forbid the luxury of a nurse the physician can do a timely service by the enforcement of a few simple rules for the relief of the suffering patient, and oftentimes he can introduce a system of attendance easily comprehended and followed. But what shall he do when he is confronted by the abodes of

"Poverty, hunger, and dirt"?

— the haunts of idleness, shiftlessness, and drunkenness; where the wretched offspring of disease and crime huddle together in the helplessness of want! It is here that he must assume the part of the philanthropist, and stoop down, and with pitying hands minister to God's suffering poor.

And can he not do more than this? Can he not, by his influence among the more favored classes, assist in the establishment of a *system of ministration* that shall result in lifting up these wretched sons of want, so that the coming generation, at least, can have some appreciation of the decencies of industry and of cleanliness. It is a noble part of the ministry peculiar to our profession to be able to inspire hope, and confidence, and an honest industry among the descendants of families that for generations have sat in the "dark by-places," with no aspiration and no purpose. And in this way something effectual can be accomplished towards arresting the frightful mortality among the children of the poor.

A noble army of women is doing a benevolent work in relieving the *immediate* wants of these poor sufferers. But in the broader and more radical work of instituting a system of distribution that shall look to a *reformation*, the physician, by his intimate knowledge of the causes of poverty and suffering, must act an important part as adviser and educator. To him, in a special sense, belongs the duty of suggesting to charitable bodies plans of operation that shall secure those practical results so essential to the substantial success of free and generous giving.

The Ethics of this Society, in their relation to a certain class of medical practitioners, are grossly misapprehended by the public. People can readily understand why we can have no affiliation with the vulgar charlatan or the arrant quack, but they do not as easily comprehend our attitude towards another class, composed largely of men of culture and high social position; men who, perhaps, were educated in the same schools and colleges, and who seem in all respects to be peers with the Fellows of this honored Society. Representatives of other professions have not been slow in their strictures, and we have been charged with bigotry, narrowness, and jealousy because of our position in this relation.

Much of this criticism arises from the ignorance of the popular mind as to the causes that compel an adherence to the fundamental principle, that the practice of medicine has a basis as broad and liberal as science itself, and therefore it cannot be limited in its universal scope by any system based upon an *exclusive dogma*, and depending for its success upon the charm of a "distinctive appellation."

We might explain to all such critics, and without any compromise of professional dignity or of self-respect, that, from the very nature of things, these exclusive practitioners are the victims of their own environment; that, by the narrowing process of their own theory, they shut themselves outside the generous fellowship of liberal thinking, and take refuge within the walls that they have built. Is this the way that "star-eyed science" conducts her votaries? Is she exclusive? Has she secrets locked up and hidden from the search of universal investigation? Is it not time that the epithets "regular," "old school," "allopath," popular nicknames coined by the opposers of science, were discarded from our vocabulary and ignored forever? We desire no other title than the simple, homely name of physician, a term broad enough to embrace all that is desirable or possible in the art of healing; that recognizes every hint or suggestion of a liberal or intelligent experience; that receives into its vocabulary the nomenclature of the honest, patient investigator, and accepts new theories, even at the sacrifice of those long cherished, but no longer practical, methods of the past.

Not long since a member of this Society was entertaining a company of clergymen around his hospitable board, when the conversation turned upon that phase of our ethics relating to the discipline of certain members. "Why is it," said a leading divine to his host on this occasion, "that your Society pursues such a severe and illiberal course toward members who differ from you in methods of practice?" The genial doctor explained that the course pursued was based upon the

[1] Address delivered at the first commencement of the Mount Sinai Training School for Nurses, May 12, 1883. By Abraham Jacobi, M. D.

same principle as that which governs all social compacts. "What would you do with a member of your religious body who denied the fundamental elements of your doctrinal statement, who assumed another and distinctive title based upon a speculation? and more than all that, who assisted in organizing and supporting a system whose principles were in direct opposition to those held vital to your existence?" "Do with him?" said the good minister, with commendable zeal, "We'd have him disciplined, and if he did n't repent and recant we'd cut him off!" "That is somewhat like our position," was the quiet and convincing reply.

A gentleman of my acquaintance, in high position in the legal profession, whose sick daughter was attended by a homœopathic physician, was highly incensed when a member of this Society declined a consultation. The judge, who could adjust a knotty point of law, failed to discern the ethical relations of this case, and the only difference that he could see between the two practitioners was that one was far more liberal and elastic in his practical methods than his conservative neighbor. He subsequently learned, however, that the cause of refusal was not based upon any narrow or selfish ground, that it did not depend upon the administration of large doses or small doses, nor upon the *belief* in any particular dogma. The fault was in the assumption of a title and the formation of an organization "distinct from, and opposed to, the medical profession."

Why not distinctly emphasize the statement, so that he that runs may read and understand, that the medical profession has no limitations except such as are made by science itself; that anywhere and everywhere a welcome is extended to all who comply with the benign and rational conditions of membership; that a profession based upon bigotry, narrowness, or illiberality cannot exist under the searching light of the nineteenth century?

Prof. Austin Flint, in his admirable digest of the Medical Ethics of the American Medical Association, uses the following language upon this important topic: "The true ground for refusing fellowship in consultations, as in other respects, is a name and an organization distinct from, and opposed to, the medical profession. Whenever practitioners assume a distinctive appellation, thereby assuming to represent an essentially distinct system of practice, taking an attitude of antagonism to the 'regular' profession, seeking popular favor on the ground that they belong to a 'new school,' based on truth and productive of good, whereas the 'regular' profession belongs to an 'old school,' based on error and productive of harm, how can there be fellowship either in consultations or in other respects? If they who thus assume an attitude of antagonism to the medical profession conscientiously hold to the distinctive tenets which, as they profess, are the ground for their antagonism, how can they consistently desire to meet members of the latter in consultation, and, with opposing views of therapeutics, how could such consultations accomplish 'the sole object in view,' namely, 'the good of the patient?'" And he adds these terse words, which possess a significant meaning: "If, as is asserted, homœopathy has practically been abandoned by most of those who practice under this name, or so modified that the modes of treatment in cases of disease are not essentially different from those of the 'regular' profession, why retain the separate organization and the name, which imply to the public a radical therapeutic distinction? If the assertion be true, the name and the organization being retained, professional fellowship is rendered thereby immoral on the ground of complicity in a fraud upon the public."[1]

(To be concluded.)

THE PLASTER-POSTERIOR SPLINT IN THE TREATMENT OF FRACTURES OF THE LEG.[2]

BY GEORGE W. GAY, M. D., OF BOSTON.

THE ideal dressing for a broken leg must be simple, comfortable, cheap, readily obtained, easily applied and removed, and must allow a frequent inspection of the limb without disturbing the patient. It must be applicable to all cases; capable of correcting any and all deformities, and of retaining the fragments in the desired position for an indefinite length of time; not liable to produce abrasions or other mischief; and once properly adjusted it should require little attention during the progress of the case.

Such an appliance has never, to my knowledge, been brought to the notice of the profession, but the one that seems to combine more of the desirable qualities than any other is the plaster-posterior splint, which has now been in constant use at the City Hospital for several years, and which has become a standard method of treatment in that institution.

The splint is made of sheet wadding, a coarse muslin or crinoline, and plaster of Paris. It may be applied as follows: The leg is washed and dried and enveloped in the cotton, which has been torn into strips about four inches wide, sewn together, and made into rolls like an ordinary bandage. Enough should be used to protect the bony processes and tendo-Achillis from pressure.

A single layer of the gauze large enough to extend from the toes to above the knee is to be placed beneath the limb, closely wrapped about it, and cut so as to completely surround it, with the exception of a space about an inch wide on the anterior aspect. This piece serves as a pattern by which the other layers, six or eight in all, are to be made. The muslin is to be slashed on each side opposite the point of the heel to allow the foot-piece to be brought to a right angle without forming clumsy folds. Other slashes may be required to make the dressing fit snugly and smoothly, and to prevent wrinkles.

Fresh plaster of Paris mixed with warm water to the consistency of cream is now to be thoroughly rubbed into each layer of the gauze, and the whole applied to the limb at once, moulded closely and carefully to it, and firmly secured with a common bandage. The fragments are to be held in their proper place until the splint has become sufficiently firm to prevent displacement, which with good plaster is not over fifteen or twenty minutes. In some cases this object may be accomplished by means of sand bags or pillows. In a few hours the outer bandage may be removed, the cotton wadding cut open with scissors, and the appliance is complete, and may be worn with comfort for several weeks.

A certain amount of judgment and tact is required to use this dressing satisfactorily, but no more than is

[1] Medical Ethics and Etiquette, page 47.

[2] Read before the Massachusetts Medical Society, June 10, 1884, and recommended for publication by the Society.

necessary in the treatment of fractures of the leg by any other method. A little experience will enable any one to become familiar with the practical details of applying this bandage, and the field of its usefulness will be found to increase in proportion to one's familiarity with it.

Particular attention is called to a few points in adjusting this plaster case. The greatest pains should be taken to hold the fragments in their proper position until the plaster sets, otherwise they may get displaced, when a new bandage will be required, or a deformity will be the result. The foot should be placed at nearly a right angle to the leg, especially if the fracture is at, or near, the ankle-joint. Little padding is required except about the heel and malleoli. Care should be taken that no wrinkles or folds be allowed to press upon the limb. The splint should reach the metatarso-phalangeal articulation below, and, as a rule, should extend above the knee, particularly in children, to prevent twisting of the fragments in their long axis, or, in other words, to hold the foot in its natural relation to the knee. It should embrace about three fourths of the circumference of the limb in order to give the desired support, and to retain itself in position.

This dressing is especially adapted to cases of simple fractures of the tibia, or of the tibia and fibula, which are not attended with serious injury to the soft parts, and in which no great amount of force is required to maintain the fragments in their proper place. It is very convenient in the treatment of these injuries in children. Applied under ether it is firm and solid before the patient awakes, and does not require frequent tinkering during recovery, as do many other appliances. The advantages of a dressing which does away with the pain and fright so commonly attending the ordinary treatment of fractures in children cannot be too highly appreciated.

Certain cases of compound fracture of the leg can also be satisfactorily treated with the plaster tray, if the soft tissues are not too extensively injured, and if the wounds be so situated that they can be exposed through apertures in the splint for purposes of cleanliness and local applications. For this class of injuries the bandage may be strengthened with strips of hoop iron, lined with oiled silk, and kept in position by means of straps with buckles.

Properly applied to the above-mentioned classes of injury the plaster-posterior splint is comfortable and efficient; it is self-retaining; it holds the fragments firmly in position; it allows the patient to be moved, or to move himself without danger of disturbing the fracture; it permits the parts to be readily examined; being opened throughout its entire length the bandage accommodates itself to the swelling of the limb without danger of strangulation; it can be applied immediately after the accident, there being no necessity for waiting until the inflammatory stage has subsided; it can be removed and readjusted with ease, and can be worn indefinitely.

The same rule in regard to opiates obtains here, as in all fractures, namely, they should never be given until the physician is reasonably certain that the dressings are doing no harm.

Contrary to the teaching of some authorities, the writer believes in frequent examinations of broken limbs until the fragments are so closely joined that they cannot be easily displaced. It must be a very exceptional case in which union is prevented by too much manipulation. Broken ribs and collar bones, though necessarily subjected to constant motion, almost always unite well. So do fractures complicated with delirium tremens, or excessive restlessness, or insubordination, in which the parts often sustain great violence.

If the physician would avoid deformed limbs, splint sores, and lawsuits, he must, by personal examination, keep himself constantly informed as to the position of the broken bones and the condition of the soft parts, even at the expense of considerable discomfort to the patient. Temporary pain caused in this manner is of little importance compared to the life-long mental and physical distress which may result from an unnecessary deformity.

The susceptibility to pain differs so greatly in individuals that it is not safe to rely wholly upon their sensations in determining the compression of a bandage. I once saw a case of gangrene of the foot, the result of a tight bandage, in which there was never any suffering. The only safety lies in watching the circulation of the toes, and in making careful examinations of the limb, being guided to a certain extent by the sensations of the patient. It is to be remembered that some persons with a fracture will always complain of pain, whatever treatment is followed. As these patients generally eat and sleep well, and remain in good condition, opiates are to be given sparingly, if at all.

The position of the fragments incased in the apparatus under consideration can frequently be determined by simply sliding the fingers along inside the splint without removing it. But to thoroughly examine the parts the tray must be forcibly sprung open and the leg carefully lifted out.

As plaster of Paris is brittle and not elastic, frequent removals of the dressing tend to weaken it. Whenever it becomes loose from this cause, or from wasting of the limb, it may be tightened with straps, or a new one may be applied. In many instances one bandage is sufficient for the entire treatment.

It is not necessary to weary you with details of cases which have been treated by the above method. Suffice it to say that not infrequently this dressing is applied to fractures of the leg at the City Hospital within twenty-four hours of the accident, and not disturbed until the fragments are firmly united and the recovery is complete.

The results obtained with this method of treatment are probably no better than those following the use of side splints, fracture boxes, etc.; but there is a great saving of time and labor to the surgeon. There is not that necessity for a frequent readjusting of splints and bandages, which is so essential with most other appliances.

The writer wishes it to be distinctly understood that this dressing is not adapted to all varieties of fracture of the leg. For example, some cases of Pott's fracture accompanied by marked eversion of foot, requiring strong pressure to restore and retain it in its proper position, can perhaps be better treated by other methods. So likewise may those bad cases of oblique fracture of the tibia, the fragments of which override each other to a great extent. Severe contusions of the soft parts should not be subjected to pressure until all danger of ulceration and sloughing has passed. The presence of blebs or blisters, however, does not neces-

sarily preclude the use of this dressing, as they may often be treated through an opening in the plaster.

It has always seemed to me that those physicians who permit their patients to move about on crutches a few days after an immovable bandage of any kind has been applied to a recent fracture of the lower extremity allow their enthusiasm to get the better of their judgment. The complications liable to occur during the repair of broken bones are so numerous, and at times so insidious, and suits at law for malpractice are so common, that in my opinion no adult should be allowed to move about until there is fair union of the tibia and fibula, which usually requires from four to six weeks, and very little weight should be put upon the limb for some time longer. There can be no doubt that deformity occasionally takes place in these cases from the patient's getting up too soon, while the union is green, thereby allowing the fragments to gradually yield under the weight of the body.

Those cases of fracture of the lower end of the fibula and rupture of the deltoid or internal lateral ligament of the ankle, accompanied with an outward dislocation of the foot, are often very difficult to manage, and require a longer confinement than any other simple fracture of the leg, three or four months being necessary in some instances to insure sufficient repair to prevent future deformity. In some of these cases it is impossible to avoid a little eversion of the foot, whatever may have been the treatment and however long it may have been continued. The writer has seen a recurrence of the dislocation after three months' confinement. He has also seen two or three cases in which the inner malleolus had been exposed by ulceration due to a return of the deformity, after a fair union had apparently taken place. He would never permit a person weighing one hundred and fifty pounds to bear his weight upon a Pott's fracture under three months, and the greater the weight the longer should be the period of rest.

A different line of treatment, however, is called for in some cases of fracture of the shaft of the long bones, more especially of the femur. When the union is imperfect at the end of three months or thereabouts, nothing does so much good as to incase the limb in an immovable bandage and get the patient up on crutches. The local irritation which results from this practice tends to excite the reparative process to that degree that the fragments become firmly united within a comparatively short time.

In conclusion allow me to say, that while I do not think the plaster-posterior splint is adapted to all fractures of the leg, yet in the classes of cases specified in this paper I most heartily recommend it, hoping that a fair trial will convince some surgeons, as it has the writer, that the dressing combines more good qualities and fewer bad ones than any of the common appliances in use at the present time.

[A practical demonstration of the plaster-posterior splint was made before the Society by Dr. R. A. Kingman, of Boston, who perfected and brought it into use in this vicinity while he was house surgeon at the City Hospital in 1881. The efficiency and popularity of the splint are largely due to Dr. Kingman's skill and ingenuity.]

REPORT ON LARYNGOLOGY AND RHINOLOGY.

BY FRANKLIN H. HOOPER, M. D.

PARALYSIS OF INDIVIDUAL FIBRES OF THE RECURRENT LARYNGEAL NERVE.[1]

IN Nos. 46–49 of the *Berliner klinische Wochenschrift*, Dr. Felix Semon, of St. Thomas's Hospital, has communicated an exhaustive paper on the proclivity of the abductor fibres of the recurrent laryngeal nerve to succumb earlier than the adductor fibres, or even exclusively, in all forms of organic disease or injury, central or peripheral, acute or chronic, which concern the motor nerves of the larynx. The general validity of this law he first stated in the *Archives of Laryngology*, July, 1881. In the papers now before us there are notes of fifty-eight carefully observed cases, with twenty-one necropsies, all of which are in strict accord with the statements Dr. Semon has made. Many of these cases have been under the author's own observation; the remainder have been reported by men of the highest reputation, and, so far, no well-authenticated case has been brought forward which would invalidate his conclusions. The undoubted occurrence of transitory and varying isolated paralysis of the abductors, which, Dr. Semon has always contended, is characteristic of functional disorder of the motor nerves of the larynx in cases of soft lymphatic goitre, is only seemingly contradictory to his teaching, as these paralyses can be explained on the theory of transitory anæmia of certain regions of the brain. The occurrence of an isolated paralysis of the abductors from central causes can only be understood on the assumption that the nucleus of the spinal accessory nerve consists of strictly differentiated ganglionic cells; and the author points out that the proclivity of the laryngeal abductors to succumb to organic disease is not a pathological curiosity, but, as Ferrier has shown in reference to the abductors and extensors of the body, a part of a general law. In conclusion, the author lays great stress on the diagnostic importance of this proclivity. He shows, practically as well as theoretically, that, in pure unilateral paralysis of an abductor, there is no alteration either in voice or respiration, so that, unless a laryngoscopic examination is carried out as a matter of routine in all cases of evident or suspected organic disease of the brain, neck, or thorax, an early and sometimes the only symptom may escape notice; and he claims, under these circumstances, for the laryngoscope the position occupied by the ophthalmoscope in the diagnosis of renal and cerebral disease. If, as it would appear from this careful and exhaustive paper, the foregoing statements are unexceptional, there can, indeed, be no doubt of the extreme importance of this fact in anatomical and physiological as well as in diagnostic respects.

APSITHYRIA.

Some years ago Dr. Solis Cohen, of Philadelphia, reported, under the title of apsithyria, several cases in which there was complete inability to whisper, as well as aphasia, a condition to be carefully distinguished from that in which the inability to whisper is only apparent, and in which, on placing the ear close to the patient's mouth, or by using an ear-trumpet, a more or less feeble whisper can be detected. The author has

[1] British Medical Journal, December 8, 1883.

recently returned to the subject in a paper in the *Philadelphia Medical and Surgical Reporter* of November 10 and 17, 1883, and records another case of this rare affection. An unmarried lady, aged forty, was seen on November 22, 1881. For fifteen months her voice and whispering power had been absolutely lost, the double infirmity compelling her to resort to tablet and pencil as her only means of personal communication. In February, 1879, she had suffered from pneumonia, which had left her aphasic; for about eighteen months she had been able to talk in a whisper, but not since. Laryngoscopic inspection revealed paralysis of the arytenoid muscle, and of both lateral crico-arytenoids. The patient was debilitated, dispirited, languid, and hypersensitive; also very deaf. The treatment consisted in the internal administration of sulphate of strychnine in gradually increasing doses, and in daily topical applications of electricity to the paralyzed muscles of the larynx, to some of the voluntary muscles of respiration, to the muscles of articulation, and to the region traversed by the pneumogastric nerves in the neck. In three weeks the ability to whisper was restored to such a degree that the tablets were given away, and have not been used since. At the end of about two months her voice began to improve, but would only reappear for a short time. After several relapses it was finally restored permanently.

Apsithyria is usually found in females, but the author has seen it twice in the opposite sex. Once it occurred in a male religious fanatic, aged about forty, in whom aphasia and apsithyria had been complete for several months. One application of the interrupted current to the vocal cords cured the aphasia and apsithyria at once. The case was evidently hysterical. And once in a man aged above thirty years, who was not at all hysterical, and in whom the aphasia accompanying the apsithyria was due to paresis of the arytenoid muscles. This patient recovered under a tonic and electric treatment. In all cases which the author has seen the ability to whisper was last lost and first regained. The aphasia with which apsithyria is associated is always, according to the author, due to a functional paresis, and is not myopathic in origin. The apsithyria is apparently paretic too, he thinks, but where the seat of the paresis is is uncertain. The author suggests that it is in the muscle of the diaphragm. It is not in the other muscles of involuntary respiration, for their functions exhibit no evidence of impairment; nor is it in the muscles of the tongue and lips, for voluntary control over these muscles is sufficiently well maintained. Voluntary expiration can usually, according to the author, be effected; but the expiratory current cannot be emitted with the force sufficient to make a sound. These patients seem to make an effort to whisper, consciously and conscientiously, but they fail.

THE PERI-TRACHEO-LARYNGEAL GANGLIONS.[1]

The authors of this interesting article consider that the importance which these lymphatic glands play in causing certain vocal and respiratory functional troubles of the larynx entitle them to a more detailed description than they have received in the works on anatomy. The name of peri-tracheo-laryngeal glands is given to designate those glands which are situated in the cervical region, between the inferior and posterior portion of the larynx, trachea, and œsophagus. They are in the immediate vicinity of the recurrent nerve, and are separated from the vertebral column and pre-vertebral muscles by an abundant and loose cellular tissue. This study is founded upon twenty dissections, both normal and pathological, and the following are the more important points established: These glands, following the course of the recurrent nerve, form a chain, and are arranged generally in three groups: —

(*a*.) The inferior group, the largest and the most constant, is continuous with the mediastinal glands.

(*b*.) The middle group, less constant than the preceding, is composed of glands so small that they may escape notice.

(*c*.) The superior group, situated near the inferior and posterior part of the larynx, is perhaps less constant than the middle group, and composed also of very small glands.

The three groups may unite and form a continuous chain. Occasionally one of the superior groups is absent. In tuberculous, cancerous, and possibly syphilitic subjects, they may become greatly hypertrophied. The symptoms arising from compression of the nerves by these glands are due either to paralysis of the vocal bands or to spasm of the glottis.

THE CLINICAL SIGNIFICANCE OF THE ACUTE SUBCHORDAL SWELLING AND THE ORIGIN OF THE CROUPY COUGH IN LARYNGITIS.[2]

Any point which will serve to make clearer the vexed consideration and classification of the various diseases characterized by hoarseness, dyspnœa, and barking cough in children is worthy of attention. Dr. Karl Dehio, the assistant of Dr. C. Rauchfuss, in an article made interesting in great part by the cases detailed, believes that he has demonstrated an ætiological factor which has not yet received much attention. Rauchfuss was the first to draw attention to the swelling of the membrane below the vocal cords as the cause of the stenosis in the laryngitis in children. Türck had made mention of such swelling in 1866, but no attention had been paid to it. Burow reported a case in 1877, and in Ziemssen's work this case, with two from Rauchfuss and two from personal observation, was described under the head of Laryngitis Hypoglottica Acuta Gravis.

Dehio's task has been to connect clinical symptoms with laryngoscopic appearances. From the large material of Rauchfuss's clinic he has made a series of laryngoscopic examinations in all cases of acute laryngitis where it was possible. He found well-marked subchordal swelling in cases of (*a*) simple *barking* cough. (*b*.) Barking cough, dyspnœa, but no loss of voice, all much less marked in four hours, and about well in twenty-four hours, showing how rapidly the swelling may disappear. Vocal cords not affected. (*c*.) The same symptoms coming on very rapidly in a younger child, accompanied with great dyspnœa and all the symptoms of false croup. Examination showed the same subchordal swelling, but here in the narrow larynx causing more nearly complete obstruction. (*d*.) Slight general laryngitis, with barking cough, and not much change of voice. (*e*.) Acute catarrhal laryngitis, with barking cough, but no change of voice or alteration in appearance of edges of cords. (*f*.) Acute laryngitis complicating morbilli, and accompanied by

barking cough and larynx stenosis. (*g.*) Laryngitis subchordalis with protracted course, and resulting in subacute laryngitis.

It may be seen from these few selections from the author's many cases that his subchordal swelling plays an important rôle in many of the laryngeal affections of children. The swelling is the puffing out of the inflammatory, œdematous infiltration of the submucous tissue, which in exactly this region is looser and richer in interstitial spaces than in any other part of the larynx. When the swelling existed alone, and was not great enough to close the larynx, the only constant symptom was the barking cough. When the larynx was closed this was accompanied by the symptoms of stenosis. These two may be regarded as the clinical manifestations of laryngitis subchordalis acuta. The cough was present in every case where the swelling was found, and in one case the mirror showed clearly that at the instant of coughing, the cords being widely separated these subchordal swellings were themselves thrown into vibration, thereby producing the barking tone.

The author believes that the seat of acutely arising laryngeal stenosis is in the subchordal region, and the real barking cough to be pathognomonic of subchordal swelling.[1]

CATARRHAL LARYNGITIS.[2]

Jonathan Hutchinson, F. R. S., etc., in the course of an address on Collective Investigation of Disease, made the following remarks: I do not think that enough is known about catarrhal laryngitis. It appears to me to be a very definite affection, in minor forms tolerably common, but in its severe ones rare. It is, in a certain way, quite distinct from croup, being entirely non-membranous. It seems to me to be more common in adults, or in those past middle life, than in others. There is a tradition that Washington died of it. Acute œdema of the larynx is scarcely a suitable name for it, since it may be produced by a variety of causes, whereas the malady to which I desire to call attention is always due to exposure to cold, and always obeys the law of true catarrhal affections in passing off completely and rapidly if the patient survive. In almost all the fatal cases which I chance to remember the cold was caught by going to church, and all were in men past middle life. In one, a gentleman of fifty-five, who but one year before had insured his life for a very large sum, being apparently in excellent health, died on a Wednesday, having caught his cold on the previous Sunday evening. In this case the death was in spite of laryngotomy, and it is possible there was pneumonia also. In the last which I have seen, and the one which has made the greatest impression on my mind, the patient, a gentleman of fifty years, attended an evening service in cold, wet weather, complained of his throat immediately afterwards, had paroxysms of extreme difficulty of breathing, and died in one of them, within forty hours of his having joined in the duties of the choir. So distinctly paroxysmal had been his dyspnœa, and so complete the remissions, that he died in his clothes, not having gone to bed. This feature of complete temporary relief had led his medical attendant into the mistake of telegraphing for me to do tracheotomy instead of at once doing it himself. The patient in the end died before either of us could get there. We were allowed to examine the body within an hour of death, and found the larynx and adjacent parts in a state of extreme congestion, with much œdema, but without a trace of membrane. I by no means insinuate that catarrhal laryngitis has been wholly neglected in systematic works, but I feel sure, from much conversation with those of large experience, that collective investigation would be likely to bring out its features much more definitely, and to add an important chapter to the clinical history of catarrhal ailments in general.

SORE THROAT IN CHILDREN.

Dr. Ashby, in the *Practitioner*, December, 1883, contributes an able article on the necessity of examining the fauces in children suffering from the different acute specific fevers. The more important forms of inflammation of the throat in children are classified under four heads: (1) simple catarrhal tonsillitis; (2) scarlatinal tonsillitis; (3) pseudo-diphtheritic tonsillitis; (4) diphtheria. In diphtheria the characteristic appearances are usually well marked about the pharynx, but there are some points which aid one greatly in deciding whether the attack is diphtheria or not. Amongst these a swelling of the cervical glands with cellulitis, or perhaps a fetid discharge from the nose, is a point strongly in favor of diphtheria. Again, the pulse is weak, the temperature is not high as a rule, the urine is loaded with albumen, and there is no rash to make one confound the attack with scarlatina. In diphtheria the onset is insidious, in scarlet fever it is sudden, and is nearly always accompanied by vomiting, often by diarrhœa. In simple catarrhal tonsillitis the onset is sudden, and the temperature rises the first evening to about 103° F., the tonsils are equally swollen, and in a few hours yellow spots make their appearance, owing to the retention of the secretion in the crypts. There is no true ulceration of the tonsils, nor sloughing of the soft palate, nor cellulitis around the cervical glands. The pseudo-diphtheritic form often resembles true diphtheria very closely, but the cervical glands are not swollen, and there is no albumen in the urine.

(*To be concluded.*)

Hospital Practice and Clinical Memoranda.

DR. J. COLLINS WARREN'S NEW OPERATION FOR RUPTURE OF THE PERINÆUM THROUGH THE SPHINCTER.

BY FRANK K. PADDOCK, M. D., PITTSFIELD.

On the 2d of March last Dr. A. M. Smith, of Pittsfield, invited me to see one of his patients with him, and consider the feasibility of performing an operation for lacerated perinæum.

The patient was thirty years of age. She had given birth to two children. The first was delivered with instruments four years previously, and did not live. The rupture occurred during this first confinement, and ever afterward she had no control of the movements of her bowels, and complained of dragging pains through her back and hips and difficulty in walking.

The second child was ten months of age, and in good health, there having been about three years between the first and second confinement.

[3] Arch. für Path. Anat. und Phys. und für klin. Med.

On examination, found the perinæum and sphincter ani torn entirely through; the recto-vaginal septum was obliterated for the distance of an inch and a half above the anus.

I advised the operation, and the patient wisely concluded to have it done at "the House of Mercy" (the Pittsfield Cottage Hospital), where she could receive the care and attention of Miss Field, the skilled nurse and matron of that institution.

I performed the operation recommended by Dr. J. Collins Warren, which consists of dissecting a flap from the posterior vaginal wall and the sides of the perineal rent, and turning this flap downward, so that the vaginal mucous membrane becomes the anterior wall of the lower part of the rectum and anus.

Six silver wire sutures were introduced and twisted. The upper one was passed through the vaginal mucous membrane, so as to draw it down into close contact with the anterior portion of the wound.

The sphincter ani was well stretched before introducing the first suture, and it closed around the flap with very little tension.

The catamenia appeared on the third day after the operation, and lasted three days.

The sutures were removed on the twelfth day, and the bowels were moved by an enema on the fourteenth. On the twenty-first day a thorough examination was made, and the wound was found united throughout, and the patient was allowed to sit up. A recent examination found the sphincter and perinæum entirely restored, the uterus in its normal position, and the movements of the bowels perfectly natural in every way.

The treatment subsequent to the operation was that usually observed; the urine was drawn for sixteen days, and the vaginal douche used four times daily.

The diet consisted entirely of beef juice and coffee, for two weeks; milk was not allowed. The first movement of the bowels on the fourteenth day was as soft as an infant's.

There was very slight rise in temperature on the third day, 100½° F. Only one dose of one fourth of a grain of morphia was given shortly after the operation.

The regular catamenial period occurred one week before the operation. The recurrence the third day after the operation was undoubtedly induced. That portion of the flap which protruded from the anus sloughed.

New Instruments.

A NEW POWDER BLOWER.

BY WALTER J. OTIS, M. D.

I WISH to call attention to Codman & Shurtleff's modification of the powder blower which I exhibited at a recent medical meeting.

The instrument here figured consists of a soft-rubber bulb, to which can be attached hard rubber tubes (A, B) of various lengths and shapes. The bulb is flattened at one end, so that it will stand upright, and is provided with a small stopper (C), to prevent the entrance of air as well as the escape of the powder when not in use. Powder may be introduced into the bulb either through a small funnel or by suction.

The instrument is manipulated by the thumb, placing the tube between the first and second fingers; or

if desired, the powder can be shaken out. This will be found a useful and handy means of insufflation in such localities as the mouth, vagina, or rectum; a separate bulb, properly labeled, being kept for each powder.

Reports of Societies.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

ADJOURNED SPECIAL MEETING.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

MAY 21, 1884.

Meeting called to order at eight P. M., DR. R. T. EDES in the chair.

The SECRETARY read a communication which he had received from the Boston Society of Arts, inviting this Society to attend a meeting of that body at the Massachusetts Institute of Technology to listen to a description of the system of heating and ventilation which has been adopted in the New Building of the Institute, and which possesses many points of interest, some of which are novel.

The CHAIRMAN then introduced the subject for this meeting, which was the continuation of the discussion upon the

EPURATION OF SEWAGE BY IRRIGATION AND AGRICULTURE,

the first discussion of which took place April 30th, and is reported in the JOURNAL, vol. cx., page 609.

MR. ELIOT C. CLARKE was first called on, and spoke as follows: "Much has been said lately of the successful disposal of sewage at Pullman, Ill., by land irrigation. It affords almost the only instance in which it is claimed that pecuniary profit has attended such a method of disposal. I have recently visited this sewage farm, and the result of my observations there may be interesting to the Society.

"Land irrigation was adopted at Pullman, not with the hope of profit, but from necessity, there being no other practicable means of getting rid of the sewage except at enormous expense. House sewage only, of which there is a daily supply of about 200,000 gallons,

is disposed of by irrigation. Rain and water used for mechanical purposes are not mixed with the sewage proper but are discharged into Calumet Lake.

"The whole sewage farm consists of 1500 acres of flat prairie, situated within two miles, or less, of the town. Of this area, however, only 150 acres were used last year in purifying and utilizing the sewage, the remainder being held for future use, or cultivated without the application of sewage. The soil is a rich loam underlaid by sand. The portion to which sewage is applied is all underdrained by pipes about six feet below the surface. About ten acres are prepared as filter beds, being more carefully underdrained than the rest, and this tract disposes, by filtration, of the sewage at such times as the crops need none or would be injured by it.

"The crops to which sewage is furnished are, chiefly, celery, cauliflower, cabbage, and other kinds of garden produce which flourish with a copious supply of water. The sewage is only applied to them at such times and in such quantities as is beneficial, principally in the morning and evening, during dry weather. Some crops, as potatoes, never receive any sewage, since it is found to injure them. The superintendent, Mr. Martin, thinks he gets earlier and better vegetables than he would from land that was not irrigated. He also believes (without special opportunities for comparison) that the crops do better with sewage than they would if simply irrigated with pure water, that is, that the sewage acts somewhat as a manure. It is evident, however, that it does not act as other manures do, because he finds that it injures the land to apply sewage to it longer than for one season. After one season's application the sewage should be omitted for a year and the land, instead, enriched with barn-yard manure.

"The profit last year from sale of crops grown on that portion of the farm irrigated with sewage was about $5000. The superintendent thinks that, had it not been for early frosts, the profit would have been $7000. In calculating this gain, however, no charge was made for rent of the land or for interest on the cost of draining and otherwise preparing it, or for the machinery and other plant necessary to raise and convey the sewage to the farm, or for fuel and attendance on the pumping engines. These items would have largely exceeded the calculated profit, so that had it been possible to have discharged the sewage by gravity into some neighboring body of water it would have been much cheaper to do so.

"Under the circumstances the result is very satisfactory. The town gets rid of its sewage without creating any nuisance. No trouble has been experienced in winter. During very cold weather an inch or so of ice forms on the surface of the filter beds, but the ground beneath remains open and the sewage soaks away. Thus the primary object of the farm, which is to get rid of the sewage at all times, is satisfactorily accomplished, and, in addition, the land is cultivated, and the value of the crops produced exceeds the cost of cultivation.

"While the result at Pullman is encouraging for those towns which are compelled to purify their sewage on land there is nothing in it to commend sewage farming to towns which can discharge into water without doing any harm thereby. The conditions for sewage farming would rarely be so favorable as they are at Pullman. At that place a comparatively small amount of sewage is to be disposed of, and close at hand is available an abundance of cheap but rich farming land, perfectly flat, and with soil especially adapted to the purpose.

"In Boston the territory south of Charles River furnishes, in dry weather, one hundred times as much sewage as Pullman. If the same ratio between acreage and sewage were preserved, Boston would need a farm of 15,000 acres, an area as large as the city proper, South Boston, Dorchester, Roxbury, Brookline, and Brighton. It is needless to say that no such area suitable for the purpose can be found within accessible distance.

"The sewage of Pullman is about three times as dilute as Boston sewage, but otherwise appears to be the same material. It is allowed to flow on to the land each morning and evening unless rains occur, when it is not used so frequently.

"The effluent water is clear and free from smell or taste, and fish are found at the outlet of the filter beds, which is considered possible only in pure water. At the opening of the sewers there is a perceptible odor, but it is the smell of fresh sewage, and not that of decay or decomposition. The superintendent of the farm resides at a short distance from the filter beds, and suffers no inconvenience from their proximity to his dwelling, and his family have never been afflicted with any disorder attributable to that cause. The centre of the farm is between one and two miles from the centre of the city."

DR. FAXON stated that he had listened with much satisfaction to the discussion, but that one element existed in American sewage which was not found in that of any European system. The sewage of every American city is loaded with tons of grease, which materially interferes with its utilization in the same manner as is followed in other countries. The greasy contamination forms a solid crust in the upper layers of the soil, which the roots of plants cannot penetrate. The Pullman farm is far from representing the actual results of such a system in its more extended adoption. The sewage from Boston is at present discharged into tidewater, but the nuisance of sewage pollution is not removed. A certain portion of Boston sewage comes to the shores of Quincy Bay, and is already creating a nuisance along the beach in that vicinity. From the windows of the Sailors' Home at that place can be seen a layer of sewage many acres in extent upon the surface of the water between that point and the neighboring islands. As summer approaches the sludge becomes more abundant, and is thrown up on the shore, where its stench becomes intolerable. Some other method than the present must ultimately be adopted for the disposal of the sewage of Boston.

If an engineer were requested to designate a perfect system of sewerage it is quite impossible to say what method would be recommended, but at present, everything taken into consideration, filtration seems to be the most available method known.

In reply to Dr. FAXON MR. CLARKE said: "This is the first intimation I have had that the Sewage Works at Moon Island create any nuisance or are likely to. Those who live on the island experience no discomfort. I have seen some sludge about the outlet, and there are places on the Works where one can get the odor of sewage. That was to be expected. The sewage which is discharged at Moon Island formerly emptied at fifty outlets in Boston, and made fifty nuisances close to residences, places of business, hospitals, bathhouses, etc. It has not been changed to cologne water by being diverted to Moon Island. But I do not be-

lieve that any nuisance will be created there which can possibly affect any one not living on the island.

"Although a little of the sewage may deposit near the outlet, almost all of it goes out of the harbor. It follows an unvarying course between Long and Rainsford Islands, and none of it ever turns into Quincy Bay. Its outward course can be distinctly traced for about a mile, but at a little greater distance from the outlet the dilution with salt water is so great that all trace of the sewage is lost."

DR. MARCY inquired of Dr. Faxon the reason why he believed the fatty matter of sewage caused the soil to mass together and thus, as stated, prevent penetration by the rootlets of plants. Dr. Marcy questioned if this could really be true, since the fatty materials of sewage are chiefly animal, and it is well known that these rapidly and easily undergo fermentation and decomposition, setting free the fatty acids at ordinary temperatures. Thus these compounds are taken to pieces by the action of the bacteria and fitted to serve as plant food. Dr. Marcy inquired as to the filtrative power of the soils as shown in the experiments of Dr. Faxon and at the Woman's Prison, saying we must bear in mind that for about six months of the year in our latitude there is very little vegetation, and provision must be made for winter sewage. Contrary to the usual belief, sand makes a most unreliable filter.

MR. EDWARD S. PHILBRICK, C. E., spoke as follows: "The subject under discussion is a very broad one, and I shall therefore limit myself to the question of applying the sewage of *Boston* to irrigate the soil. While not wishing to be understood as opposing the system of irrigation by sewage in general, and while recognizing the importance of making strenuous efforts to prevent the pollution of water supply by a reckless discharge of sewage into natural water courses,[1] I will refer to some of the obstacles which tend to render sewage irrigation a difficult plan for this city.

"The money value of the solid and dissolved ingredients of sewage has been urged by many persons who have investigated the subject. Many skilled investigators have devoted their attention to this question, particularly in Europe, within the past ten years, and we have much information from that source as well as from the experiments made by European towns in the disposal of their sewage by irrigation.

"But the money value of the ingredients of sewage is by no means the only question of importance in the consideration of its disposal. It has often been found in developing mines that the number of pounds of copper or silver in a ton of ore, as determined in the laboratory by assay, is but a poor guide in deciding upon the value of the ore or the mine. We must also know what it costs to stamp, wash, and smelt the ore and refine the metal that exists in that ore before its commercial value can be established. So in the disposal of sewage by irrigation it has often been found impossible to recoup the cost of the process by the product of the farm. The disposal of the sewage in some *innocent* way is necessary to the welfare of the community, so that for sanitary reasons such a course may often be the very best, though no source of profit, simply because it is the cheapest way of getting rid of a dangerous material; but it should not be regarded as likely to be *profitable* as a commercial undertaking, except under the most favorable circumstances.

"The difficulties met with are such as these: Plants that are useful as farming products do not tolerate a constant saturation of the soil they grow in. Therefore a sufficiently large area of soil must be treated to allow of applying the sewage on alternate fields, so that one may be receiving it while it is soaking away on the other. Even then we find that the plants which need a copious supply during a certain stage of their growth need much less at other stages when approaching maturity. We find, too, that the crops which are benefited by a large quantity of fluids in a dry month would be destroyed if an equal amount were put on the land in a rainy month. Now since the flow of sewage from any city is likely to be rather more copious in a rainy period than in a dry one, even though pains may be taken to exclude the rainfall from the sewers, the crops are often drowned with sewage at one time while getting barely enough to supply their wants at another. For this reason those sewage farms have been most successful where the farmer was not obliged to take the *whole flow*, but merely what he desired from time to time.[2]

"In order to make sewage irrigation successful the land must be located favorably, must not be too steep in its declivities, and must be had at low rates of cost, that is, consistent with prices paid for other farm lands. Such a surface is not easily found near Boston.

"However great the advantages of irrigation may be to certain crops, it is not so applicable to hoed crops as to the grasses, for the reason that irrigation puddles the surfaces, which unless very sandy cakes and hardens when drying, requiring frequent hoeing to pulverize the soil. Therefore it has been found that Italian rye grass is the best crop for sewage irrigation. But this is a crop which is poorly adapted to our climate and is of little value except for soiling cattle. Moreover we have in this climate at least six months of every year when no such crop can be grown, while the flow of sewage is continuous during the year."

MR. DESMOND FITZGERALD, C. E., said that the improved system of sewerage for the city of Boston was so designed that if it should ever be found desirable to utilize the sewage, it could be done, but that in the present experience of dealing with as large a quantity of refuse water as that now supplied by Boston, and considering its highly diluted state, it would be a great waste of money to attempt any scheme of utilization. In regard to inland towns situated on the borders of water-sheds used for sources of water supply, the case was, however, far different. Here very small amounts of sewage had to be dealt with, and there was little doubt in his mind that some scheme either of filtration or irrigation could be successfully applied. The speaker did not intend to use the word success in a pecuniary but in a sanitary sense.

Mr. FitzGerald proceeded to describe the actual condition at the present time of the several sources of supply of the city of Boston, and of his attempts to preserve the purity of the same. He showed that the time had now arrived when some principle of action must be assumed. Either the brooks must be given

[1] It seems to me that Dr. Barnes has informed himself chiefly by *reading*, and that his reading has embraced only one side of a question which has been attended with a very warm *partisan* discussion in England lately. I hope its discussion here may be more deliberate and of a broader character. One thing is certain in my mind, namely, that it is a *local* question very largely, and that *patent systems* are no more likely to be widely applicable in our profession than in your own, and for similar reasons.

[2] The success of the Genneviliers sewage farms, as I am informed, is attributable to this fact, that the delivery of sewage to the farmer was at his option and not obligatory. Such a system can never be a reliable source of relief to a town so long as any considerable portion of its sewage flow is liable to be left undisposed of in a wet day.

up to the towns for common sewers or the towns must be made to take care of their sewerage in a proper manner.

The speaker went on to show that the brooks are now used for drainage only by those people who happen to own land on the margins, while the neighbors immediately adjoining have to provide for their sewage by emptying their cesspools, etc., and the hardship and injustice of this is not denied. Mr. FitzGerald described the works at Sherborne, which are sub-surface irrigation combined with intermittent downward filtration. He said the works had been very much misrepresented, and that while no filtration system removed the chlorine, yet the effluent water was clear and inoffensive to the eye or smell, and practically the filthy condition of the sewage is very materially improved. The speaker agreed with the statements made by Mr. Ernest W. Bowditch at the last meeting, that no cast-iron rule could be made to suit all cases, but that as the circumstances and situation of every town were different, so a study would have to be made of each case and that system adopted which best suited its peculiarities.

DR. JOHN G. BLAKE remarked that, looking at the subject from the health stand-point alone, it was becoming every day more necessary that some solution of the sewage question must be attempted if the health of communities as affected by their water supply was to be considered. What is wanted to hasten the solution of the subject is a law compelling towns bordering on rivers, ponds, and lakes to make some other disposition of their drainage than to allow it to run into these as receptacles. Up to the present time it has been impossible to convict offenders, but during the past winter a law, more stringent in character and free from the defects in previously existing laws, was passed, and under it, action to punish offenders will soon be commenced and pushed vigorously. From what had been said on the subject Dr. Blake is inclined to think that irrigation might prove itself very well adapted for small country communities without any regular system of drainage. The question of profit might well be left for later discussion, and the only point deserving consideration was the disposal of their sewage at the least expense and in such manner as to prevent its becoming a source of injury to themselves and others. Inasmuch as eighty cities and towns are moving to supply themselves with water, the importance of this subject had become very much magnified, and action looking to a remedy must soon be taken.

DR. BARNES, in closing, said: If the theories advanced in opposition to the employment of irrigation and agriculture for the epuration of sewage had not been used in Europe, and finally overcome by actual experience, one would hardly feel like continuing to advocate this system for Massachusetts. My enthusiasm, however, does not carry me so far as to suggest even a possibility of the abandonment of Boston's system of intercepting sewerage, notwithstanding the probability of its polluting the lower harbor and producing an unsanitary condition similar to that of the upper harbor, and an annoyance to the people living on the south shore, for before this condition is reached it may fairly be anticipated that irrigation and agriculture will have proved here, as in Europe, an economical and practical method of epuration. The sewer can then be extended to the main land and discharged on the soil. "It will not be possible, however, to connect any territory adjacent to Boston with this system without constructing an additional tunnel under Dorchester Bay." This is the language of one of Boston's officials a few weeks since before a committee of the Legislature. Filtration has, in numerous instances in Europe, accomplished complete clarification of sewage, and yet the analyses show the effluent water to contain from one half to six sevenths of the original amount of polluting matter. Colonel Waring's system of filtration at the Women's Prison accomplishes all that is possible, and yet the analyses show the result to be far from satisfactory. Pasteur and Shloesing, with others, sign a report to the Parisian government in which is stated, "The system of epuration by soil is the only one yet demonstrated to be a success. The discharge should be intermittent, and with methodical rotation, and the doses should be determined by analyses of the effluent water."

At Dantzic is encountered a mean winter temperature about that of our own. Irrigation is continued throughout the year with quite as much success in epuration in winter as in summer, and at all times without offense.

The "winter basins" at Breslau are not a part of the system advocated, as they involve the stagnation of sewage.

"The rosy coloring" of the Gennevilliers farms was not my own painting, but the translation of a report by a commission appointed by the city government of Paris, to whom, it seems to me, ought to be accorded the credit of knowing the facts, particularly as the report was unanimously signed. These gentlemen say "the increase in valuation and population at Gennevilliers is due to farmers coming from other parts of France to share in the general prosperity." Durand-Claye says "the population of Gennevilliers has increased thirty-four per cent. in five years by the arrival of numerous cultivators." M. Joly says of the Gennevilliers farms: "The question, scientific and practical, is absolutely solved." And Dr. Loiseau, at the Geneva Congress, in 1882, said "the benefits derived from these farms are indisputable from every point of view."

I was amazed at the statement that no person knew the cost of the Gennevilliers farms, as I have in my library an official document of Paris pretending to give every item of expense from the first experiment at Clichy, in 1867 and 1868, down to 1882, including lawsuits and large indemnities paid for an unfortunate experiment.

In regard to the city of Pullman making arrangements to pump the sewage into the lake I have the following letter from the superintendent of the farm: —

RIVERDALE, COOK COUNTY, ILL., *May* 9, 1884.

DEAR SIR, — If any such arrangements as you speak of in yours of 6th inst are being made I have no knowledge of the fact. The sewage is thoroughly purified by filtration, creating neither offensive odor nor nuisance of any kind.

The farm, last year, paid over six per cent. profit on the money invested ($80,000), and we hope this year to do even better. Consequently there exists no necessity for any such change as you speak of.

Very respectfully, E. T. MARTIN, *Superintendent.*

HENRY J. BARNES, M. D., BOSTON, MASS.

It should be mentioned here that downward intermittent filtration is a valuable auxiliary to sewage farming. I. Bailey Denton has written considerable upon this branch of the subject. I regret not knowing the history of the Pullman farm, as I should like to

pay a proper tribute to the pioneer of this system in America.

The unprofitable results of sewage farming have been dwelt on by most of the opponents of the system, forgetting that it is a question of sanitation and not of making money, and if raising vegetables contributes in any degree to lessening expenses it takes precedence in a financial point of view of all others, as they make no return for the original outlay except the almost universal offense they create.[1]

It has been a long and costly struggle to demonstrate the fact that sewage can be epurated by irrigation and agriculture. Every conceivable danger has been predicted. And many are the unfortunate and disastrous experiments which can be cited as swelling the cost above the possibility of many of the farms earning interest on the plant. To obtain an act of Parliament authorizing the establishment of a sewage farm often requires the expenditure of £10,000. Litigation and land damages, another large amount, for land is very dear in England. The heavy clay soil demands a large expenditure for drainage. But notwithstanding these obstacles the number of farms has rapidly increased, until now there are at least two hundred.

The Royal Commissions recommend the enactment of a general law authorizing farms of this character.

In 1876 Messrs. Chesbrough, Lane, and Dr. Folsom, Commissioners reporting on the sewerage of Boston, say "the Edinburgh farms are profitable." One of the commissions appointed by the Parisian government declare the sewage farms at Gennevilliers profitable, and use this as one of the arguments in support of their recommendation to the city to purchase the State lands in the forest of St. Germain. The owner of the farm at Leamington (which, by the way, has not been leveled) as well as the superintendent of the farm, claim a good profit after paying the city $2250 per year for delivering 1,000,000 gallons each day at the highest point of the farm.

Mr. Aird could not have lost a large amount of money in his contract to take the sewage of Dantzic, for some years later he made a similar contract with the city of Breslau. But it ought not to be required of the friends of this system to show profit until at least one system is devised capable of competition with this in producing satisfactory epuration.

The enormous dilution of sewage in this country is mentioned as an objection. By analyses the amount of organic matter in the sewage of American and European cities varies but a trifle. Boston consumes more water per capita than Paris. But the latter city dilutes her sewage equal to that of our own by a lavish use of water in washing the streets each morning. And the estimate of three barrels of water to the discharge of one individual here does not include the organic matter constantly discharged from sink drains or the street washings. Durand-Claye, the celebrated French engineer, to whom the world owes a debt of gratitude for demonstrating the possibility of epuration by this method, says, "It is desirable and necessary that there should be a great dilution by water in order to insure rapid transit."[2]

The soil does not clog where systematic irrigation is practiced. The thin skin of impervious deposit, when dried, shrinks, cracks, and breaks up, the organic matter decays, and the soil is more pervious than where irrigation is not employed. Reservoirs of deposit are used to eliminate the coarse particles, as their decay on the surface would cause an offensive odor.

It is highly probable that the failure mentioned as resulting from an impervious deposit where "sewage was pumped on a garden," was due to puddling. And that it is an unnecessary accompaniment to irrigation is proved by the employment of this system at Buntzlau on fifteen hectares for over two and a half centuries, and at Edinburgh for over two centuries, without diminishing the permeability of the soil.

As to the impossibility of obtaining suitable soil of sufficient area in Massachusetts for the general employment of this system, the success which has attended the efforts of the English in finding it in their thickly populated island is an answer. Our forests could be utilized with little expense, and next to Italian rye grass the trees would prove the best absorbers of filth. A few acres of willows at Windsor take care of the sewage of twelve thousand people.

I recall but one other objection, the comparatively large rain-fall here, forty to fifty inches per year. At Gennevilliers 312 inches of water is sent on the land each year, and this "without making it damp or marshy since the establishment of subsoil drainage." And I know of two farms in my native town, in Worcester County, where irrigation with brook water has been practiced with advantage. Our average rain-fall is a little larger than that of Great Britain, where it is from forty to forty-five inches per annum, but the yearly average humidity (between eighty and eighty-six) is nearer the point of saturation there than here, where it is about seventy. Dr. Frankland considers the vapor in the atmosphere of England as "reducing the temperature from fifteen to twenty-five degrees;" and Tyndall remarks that "the abundance of atmospheric vapor hinders the radiation of heat at night in England." The protracted droughts which are so common in this country are unknown in England, where vegetation never suffers for want of moisture. I am indebted to Dr. Bullard for facts and figures on this branch of the question, which enable me to say with positiveness that the meteorological conditions of our climate, with the possible exception of winter temperature, are far superior to those of England for the employment of irrigation and agriculture.

To-day I only ask that before building a metropolitan sewer for the eastern part of the State to discharge in tide-water, and thus repeat the now demonstrated errors of London, Brighton, and Torquay, irrigation and agriculture may be tried, on a limited scale, by some one having faith in the success, as we might ultimately desire to reverse the current of the sewage of the metropolitan district.

A large proportion of our rural population have gardens attached to their houses. I would discourage the use of cess-pools and recommend the use of these lands for the disposal of sink water. I am informed that Dr. Jewett, of Northborough, has for many years

[1] It would hardly seem necessary to affirm before a scientific body of men that clarification is not purification, or that no system of epuration of sewage is satisfactory which by analysis shows quite as much pollution in the effluent as in the influent water. (See analysis of the sewage of the Women's Prison.) As to the average rain-fall of Great Britain the figures quoted were obtained in the office of the United States Signal Service and from Professor Niles. But as it is more a question of average humidity which determines the evaporating power, a few inches more or less of rain-fall per year is of little consequence.

[2] Babut du Maris quotes Dr. Carpenter as saying "the more dilute the better."

employed this system, and I have practiced it myself for ten years with complete satisfaction.[1]

Victor Hugo, in Les Miserables, describing the sewerage of Paris more than twenty years ago, makes a vivid picture of our systems at the present time. He writes as follows: —

"*The Earth Impoverished by the Sea.* Paris throws twenty-five millions a year into the sea. And this without metaphor. How, and in what manner? Day and night. With what object? Without any object. With what thought? Without thinking. For what return? For nothing. By means of what organ? By means of its intestine. What is its intestine? Its sewer. . . . Science, after long experiment, now knows that the most fertilizing and the most effective of manures is that of man. The Chinese, we must say to our shame, knew it before us. No Chinese peasant, Eckeberg tells us, goes to the city without carrying back, at the two ends of his bamboo, two buckets full of what we call filth. Thanks to human fertilization, the earth in China is still as young as in the days of Abraham. Chinese wheat yields a hundred and twenty fold. There is no guano comparable in fertility to the detritus of a capital. A great city is the most powerful of stercoraries. To employ the city to enrich the plains would be a sure success. If our gold is filth, on the other hand our filth is gold. What is done with this filth, gold? It is swept into the abyss. We fit our convoys of ships, at great expense, to gather up at the south pole the droppings of petrels and penguins, and the incalculable elements of wealth which we have under our own hands we send to the sea. All the human and animal manure which the world loses, restored to the land instead of being thrown into the water, would suffice to nourish the world.

"These heaps of garbage at the corners of the stone blocks, these tumbrils of mire jolting through the streets at night, these horrid scavengers' carts, these fetid streams of subterranean slime which the pavement hides from you, do you know what all this is? It is the flowering meadow, it is the green grass. It is marjoram and thyme and sage, it is game, it is cattle, it is the satisfied low of huge oxen at evening, it is perfumed hay, it is golden corn, it is bread on your table, it is warm blood in your veins, it is health, it is joy, it is life. . . .

"Statistics show that France alone makes a liquidation of a hundred million every year into the Atlantic Ocean from the mouths of her rivers. . . . The cleverness of man is such that he prefers to throw this hundred million into the gutter. It is the very substance of the people which is carried away, here drop by drop, there in floods by the wretched vomiting of our sewers into the rivers, and the gigantic collection of our rivers into the ocean. Each hiccough of our cloaca costs us a thousand francs. From this follows two results: The land impoverished and the water infected. Hunger rising from the furrow, and disease arising from the river. . . .

"A system of elementary drainage, as simple as the lungs of a man, and which is already in full operation in several villages in England, would suffice to bring into our cities the pure water of the fields, and send back into our fields the rich water of the cities, and this easy see-saw, the simplest in the world, would retain in our possession the hundred million thrown away.

"The present system does harm in endeavoring to do good. The intention is laudable, the result lamentable."

On motion of DR. HENRY I. BOWDITCH, it was

Voted, "That the thanks of this Society be tendered to the scientific gentlemen, not members of our body, who have contributed so much to our instruction and to the great interest of these meetings."

Adjourned at eleven o'clock.

[1] In view of the well-known results of chemical analyses of sewage the question as to its fertilizing properties seems to be out of place. It is almost the only fertilizer the Chinese employ. "The Duke of Portland used nothing but sewage on his farm at Mansfield, and obtained a net return of about $125 per acre." (Babut du Maris.)

PHILADELPHIA CLINICAL SOCIETY.

G. BELTON MASSEY, M. D., RECORDING SECRETARY.

JUNE 27, 1884. The President, DR. HENRY BEATES, JR., in the chair.

DR. G. BELTON MASSEY read a paper on

TRAUMATIC SCIATICA AND ITS RELATION TO HIP INJURIES.

Details of six cases were related, in the majority of which the sciatica had been overlooked, while attention was directed to a search for osseous injury. In the first case he was called in consultation to see an aged gentleman who had fallen on an icy spot of pavement eleven days previously. In falling he struck heavily on the left hip, and it was with difficulty that he arose and walked home, a distance of four and a half blocks. His family doctor, a prominent physician and an expert diagnostician, when called in searched diligently for fracture, but could find none, notwithstanding the evident helplessness of the limb and the attacks of excruciating pain that was made worse by movement. At the time the reader was called in the physician had about concluded that the pain must be imaginary.

On examination the absence of any kind of fracture was apparent. The patient could lift the limb but a few inches from the bed. He was suffering from continuous and severe pain, felt most at points corresponding to the sacro-iliac notch of the affected side — the rear of the head of the fibula, and the rear of the external malleolus. The pain was aggravated by any movement, but especially by flexion of the thigh and extension of the leg. It was clearly a case of sciatica caused by contusion of the nerve in falling.

At the request of the medical attendant the reader of the paper joined him in the care of the case, and applied the continuous descending galvanic current to the affected nerve, ending each sitting with a series of muscle-contracting interruptions of the current, great gentleness being required at first to avoid aggravating the pain temporarily. Good effect was manifest after the first visit, and eleven applications sufficed to establish a complete cure, recent careful inspection failing to detect either awkwardness of gait or atrophy of the posterior muscles.

CASE II. was that of a German woman, aged seventy-three. On the 15th of January, 1883, she fell on the ice, fracturing the neck of the femur outside the capsular ligament. After being totally neglected for two weeks, a member of the family asked the reader of the paper to take charge of the case. He found the limb one and one quarter inches shorter than its fellow, and greatly everted. At the seat of injury the

great trochanter was lost in an abundant deposit of callus. No crepitus could be found. Great pain existed throughout the distribution of the large sciatic nerve, being especially felt in the peroneal and posterior tibial branches. Considering the age of the patient, and the attempt at union already made by unaided nature, it was deemed unwise to interfere with the broken bone, so remedial efforts were entirely directed towards the relief of the sciatica. A series of blisters were directed; chloroform injections made; various stimulating and anodyne liniments applied, together with the internal administration of opiates and sedatives, but he felt bound to say the case seemed slowly to improve without being affected by any of these remedies. Electricity was not used, as the patient was too far from the office to make it possible to apply it with sufficient frequency, and the friends declined to have her removed to a hospital. The pain continued over a year in gradually decreasing severity, and though the patient has now been able to walk with crutches for some months there is much atrophy of the muscles supplied by this nerve.

The remaining four cases were selected from the large number of cases of sciatica treated by the writer at the electric clinics of the Orthopædic Hospital and Infirmary for Nervous Diseases.

CASE III. A healthy hod carrier was sent from Dr. Wharton Sinkler's clinic November 16, 1881. Seven weeks before, while carrying his usual burden up a ladder, the right foot slipped on a stick and threw the thigh into extreme flexion. He immediately felt an acute pain at the point of emergence of the sciatic and following that nerve down the thigh into the peroneal. It was sharp and pricking in character and had remained continuously present since the accident, being worse at night. He was unable to walk more than a block at a time, and presented a gait markedly characteristic of sciatica. No atrophy was found. He was placed upon static electricity, positive sparks being drawn from the painful points and course of the nerve. After the fifth application it is noted that he was much better; after the twelfth that he walked three miles to the hospital, and after the twenty-second application he was discharged cured.

CASE IV. A carpenter, aged sixty-eight, was sent from Dr. Sinkler's clinic September 29, 1880. A healthy man; eight months before admission he fell on the ice, striking the right hip. He was compelled to remain in bed six weeks, suffering from pain in the region of the small and great sciatics. His physician was uncertain whether fracture was present or not. On examination, the gluteal and flexor muscles of right leg were found much atrophied. He complained of great pain in the course of right sciatic to knee, and also in the distribution of the external peroneal. At times felt some pain in left leg. He was placed on the constant galvanic current thrice weekly. At the end of forty-two applications he is noted as entirely well.

CASE V. A man, aged forty, was sent from Dr. S. Weir Mitchell's clinic May 6, 1881. Four months before he had fallen and dislocated his right hip. This was reduced shortly afterwards and he remained in hospital eleven weeks, during which time, and up to his appearance at the clinic, he suffered from much pain throughout the sciatic distribution of that side. There was considerable atrophy of the buttock and limb — a difference of one and a quarter inches being found six inches below the trochanters. He was placed upon five grain doses of potass. iodide and the constant current thrice weekly. After thirty-five applications of the battery and considerable quantities of the iodide it was found that the pain had ceased but that some atrophy remained.

CASE VI. A porter, aged thirty-nine, was sent from Dr. Mitchell's clinic June 30, 1881. Fifteen months before he had been crushed between a platform and a moving car, fracturing the pelvis on the right side. At his first appearance at the clinic some crepitus was still present, and there was two inches shortening of the right leg. He complained of much pain in the region of the sciatic nerve of the right side, which was increased by motion and exercise. He had been blistered and was taking five grain doses of the iodide when sent to the electrical clinic. After twelve applications of galvanism, with some benefit, the summer vacation compelled a discontinuance, and he did not reappear in the autumn.

The obvious conclusions to be drawn from these cases were stated as follows:—

(1.) Surgeons called to cases of hip contusion or suspected fracture should not fail to search for evidences of injury to the delicate nervous structures here situated.

(2.) If such evidences of nerve injury are found, prompt and energetic measures of relief are indicated, the importance of which is emphasized by the complete and rapid recovery of the two cases which were treated early.

(3.) Of the four remaining cases one was distinctly benefited and two cured by more or less long-continued (one to five months) galvanic treatment. The fourth did not receive galvanic treatment, and was fully a year in duration.

DR. E. E. MONTGOMERY inquired how many cells had been used in the treatment. He thought that, considering the usual obstinacy of the class to which the cases related belonged, due to the inflammation of the sheath of the nerve, the treatment had been satisfactory.

DR. L. BREWER HALL related the details of a case similar to those described, which had been caused in a lady by a fall from horseback, alighting on the seat. The pelvis was fractured and a long continued sciatica supervened.

DR. MASSEY, in closing the discussion, said that the number of cells used varied from twenty or thirty to fifty, the kind being the gravity cell, which, owing to great internal resistance and the nature of the elements used, did not furnish as much current per cell as the zinc and carbon batteries charged with acid. The number used was largely regulated by the varying resistance of the skins of different individuals, some skins permitting a free flow of the current while others presented an almost insurmountable obstacle. It is to be regretted that the inventors have not as yet presented us with an instrument that will conveniently inform the operator of the true amount of electricity passing at a given moment. An approximation, however, to accurate dosage, may be made by including a galvanometer in the circuit, or even by observing the sensations of the patient. Since the date of these cases he had used the static form of electricity in many cases of ordinary sciatica, and found it at times equally efficacious as galvanism as well as more convenient.

FISSURED NIPPLES.

DR. DU BOIS called attention to the value of *bals. Peru* as an application for *fissured nipples*. It should be applied after nursing about four times daily.

DR. HALL, on behalf of the Committee on Microscopy, presented an improved clinical microscope, which combined all the features of a clinical with those of an ordinary table stand.

Recent Literature.

Wharton and Stillé's Medical Jurisprudence. Fourth Edition. Volume II. Poisons. Edited by ROBERT AMORY, A. B., M. D., and EDWARD S. WOOD, A. M., M. D. Philadelphia: Kay & Brother. 1884.

Excellent evidence of the revival of interest in medico-legal studies is found in the publication, during the past few years, of new books and of new editions of older works relating to forensic medicine in all its branches. Medical jurisprudence having for its aim the application of all departments of medicine to the needs of the law, it is absolutely necessary that the text-books and treatises upon the subject should be revised sufficiently often to recognize and represent the great advances in medical science which every one acknowledges. Perhaps no chapter of legal medicine stands in greater need of this frequent revision than that of toxicology. Not only is the practical art of chemical analysis a fine example of constant progress, but the fruitful labors of those who make physiological chemistry and micro-chemistry a special study should not be disregarded. Therefore it is a pleasure to announce that a new edition of Wharton and Stillé's great work, worthy successor of Beck's well-known treatise, has been prepared, and that the subject of toxicology, which in the last edition occupied a portion only of one of the volumes, along with the topics of wounds, signs of death, pregnancy, abortion, infanticide, identity, and rape, has been admirably elaborated by its former author, Dr. Amory, with the assistance of the accomplished professor of chemistry in the Havard Medical School, so that it fills an independent volume, containing more pages than the entire book of which, in 1873, the study of poisons formed a part.

The changes which the new edition shows are mainly in the nature of needed additions. Thus new poisons, such as carbolic acid, chlorate of potassium, gelsemium, physostigma, aniline, nitro-glycerine, and the nitrites of amyl and ethyl, are discussed, and new analytical methods as, for example, Dragendorff's process for the isolation of organic principles, and Stas's treatment of organic mixtures, are given in full detail. At the end of the book a very useful compilation of illustrative cases of poisoning is printed, which, though not inclusive of all the most important examples of toxicology in recent years, is ample to serve its purpose. Among these are to be found concise notes of the Lamson case (aconitine), the Major case (strychnine), the Bocarmé case (nicotine), with others quite as instructive. It is gratifying to our local pride to observe that the transactions of the Massachusetts Medico-Legal Society have received appreciative recognition from the authors. A conspicuous instance of this is found in the reproduction of the article on alcohol, read before the Society by Dr. Sabine.

In the matter of definition and classification of poisons the new volume does not depart materially from the former editions, but some changes are to be observed in the descriptive terms used, and in the distribution of individual poisons to their appropriate class. Thus in the new edition we have "non-metallic" and "septic" divisions of the irritant class instead of the "metalloidal" and "animal" divisions of 1873. Under the head "Narcotics" of the new edition are discussed chloral hydrate and belladonna, previously classed as "miscellaneous," while hydrocyanic acid, which was "narcotic" in 1873, is now found with nux vomica, aniline, aconite, and lobelia under the head "Miscellaneous." Doubtless the classification adopted by the authors is more to be commended for its convenience than for its exactness.

This volume is not, and does not pretend to be, a complete and exhaustive treatise on toxicology; but as a safe and sufficient guide upon the matters to which it relates, representing the latest advances in toxicological science, it should have a place in the library of every one who has any interest in the theory and practice of legal medicine. D.

TREATMENT OF OPHTHALMIC MIGRAINE.

FÉRÉ writes on this subject in *Le Progrès Médical* (June 7th), as follows: —

Migraine is generally considered by those who suffer from it a disease whose treatment is hopeless. These patients become accustomed to their suffering and rarely resort to the physician. There is, however, a form of migraine, the ophthalmic, characterized by the existence of a scintillating or hemianopic scotoma, a suborbital pain, nausea, and vomiting, which deserves more attention. This migraine, indeed, instead of showing itself in this relatively benign form, may be accompanied by other phenomena such as aphasia, monoplegia, hemiplegia, and partial epilepsy. Moreover, these phenomena after having been for a long time transitory may become established as a permanent state, making the victims true invalids. Among these collateral phenomena capable of becoming permanent, aphasia is one of the most frequent. The complications of aphasia may also in some cases be present. M. Charcot recently showed at his clinic such a patient, in whom was a combination of word-deafness and blindness, of agraphia and logoplegia.

Ophthalmic migraine, at least in its complicated forms, should not be considered a benign affection. It has, on the contrary, a grave prognosis, since by a repetition of attacks it may induce a serious infirmity. Hence M. Charcot insists in such cases on the employment of active treatment. In a certain number of cases he succeeded in lessening the frequency and gravity of the attacks by the use of bromides which he employed as in the treatment of epilepsy. This method consists in giving bromide of potassium (or preferably a mixture of bromides of potassium, sodium, and ammonium) in increasing doses for three or four weeks, then returning to a dose equal to or a little larger than that at the time of beginning, according to the result obtained, and so continuing. By this mode of administration it is aimed to avoid the accidents of bromine accumulation.

It must be remembered that this treatment has a chance of success only when the symptoms are not the result of material lesion, as happens, for instance, at the onset of general paralysis.

Medical and Surgical Journal.

THURSDAY, JULY 24, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY, No. 4 PARK STREET, BOSTON, MASS.

HEALTH OF THE CITY OF BOSTON, 1883-84.

THE twelfth annual report of the Boston Board of Health will, under existing circumstances, be consulted with more than usual interest by those having a direct stake in the general health and sanitary condition of the city, and this year even those dwelling without the urban limits have an immediate interest in the condition of all our sea-board towns. The Boston Board of Health in the present report makes a good showing for this city, and one calculated to reassure those who read it.

Up to May 1st there had been no occasion for alarm on account of any of the prevailing diseases, and the city had not been visited by any epidemic. The total number of deaths from all causes for the year was 9740; the estimated population in May, 1883, was 427,940; the actual death-rate was 21.91 per thousand. The percentage of deaths from preventable causes to the total mortality was 26.19, a decrease of 1.42 when compared with the previous ten years. There has been an unusual prevalence of scarlet fever and diphtheria, and the previous recommendation is strongly emphasized that sufficient hospital room be added to the City Hospital for the proper care and isolation of every case of contagious disease like diphtheria, scarlet fever, and measles as soon as settled that it cannot be properly isolated at home; only with such accommodations can these diseases be successfully combated and their mortality reduced. There has been only one death from small-pox, showing what may be accomplished by vaccination and isolation; in the last ten years there have been only twenty-five deaths from this disease, while in the single year preceding there were 302 deaths. That year, however, was one of epidemic. The percentages of deaths under five years to the total mortality was 37.23, against 35.03 the previous year, the average for ten previous years being 40.

In regard to sewerage, the report reminds the city that there is still much to be done in order to reach and drain the territory that was included in the original plan for improvement, and says: —

"The town of Brookline, the Brighton District, a portion of the North End, a large portion of South Boston, and the Dorchester District are now discharging sewage into shallow water or upon the flats, and thus perpetuating nuisances which ought to be speedily corrected by a large extension of sewers. The full capacity of the new sewer is not yet utilized, and will not be when the places named are served. There are also many places in Roxbury and West Roxbury well built up and served with water from the public pipes, but without public sewers or any adequate means of getting rid of so large a quantity of sewage. No better expenditure of money can be made than by extending the sewers to relieve these places."

Muddy Brook is still a source of distress to the abutters, to the Board who still superintend it, and of possible danger to the city. It is hoped the time is near when it will pass under the control of the Park Commissioners.

The question of Metropolitan Sewerage is forcibly and justly commented on as follows: —

"It is now five years since we began recommending a metropolitan system of sewerage for the cities and towns on the north side of Charles River and in the Mystic River Valley. The scheme has, from time to time, been favored by nearly all parties concerned. It has been sanctioned or recommended by several Governors, and by a commission of experts appointed by the Governor to consider and report upon the subject. There seems to be no reasonable doubt about the urgent need of this great sanitary measure, but there is a lack of interest in pressing its merits before the Legislature.

"The people of Cambridge, Somerville, Charlestown, Watertown, Arlington, Medford, Malden, Chelsea, and East Boston have great cause to move in this matter, for already the streams and flats to which their sewage has so long been directed are in a condition requiring immediate attention. It should be borne in mind that however bad the nuisance may be to-day it will be much worse at the end of five or six years, — the time which would be required for building the needed sewers.

"The Board would respectfully suggest that our city is vitally interested in the abatement and prevention of this nuisance, and ought to be the foremost in an effort to remedy the evil. The Legislature, at its present session, passed a bill providing for the appointment, by the Governor, of five persons to act as a commission to consider and report a plan for sewering the metropolitan district, and we trust that there will be a strong concurrent action of the cities and towns interested to bring about this great public improvement."

The number of houses ordered to be vacated during the year was sixty-six. Of these only eight were actually vacated, the owners of the others having complied with the conditions of the notice.

The whole number of prosecutions for violations of the laws and regulations pertaining to the public health during the past year was ten. There were eight prosecutions for scattering salt upon the horse-railroad tracks, in all of which convictions were had, and fines and costs imposed to the amount of $135. The sum total of all costs and fines imposed in all prosecutions during the year was $161.05.

The public baths required an appropriation of $15,000, and were patronized by 815,358 bathers, of

whom 634,418 were men and boys, and 180,940 women and girls.

The reports of the City Physician and of the Port Physician show an uneventful year.

AN OVERCROWDED PROFESSION.

THE Rev. T. T. Munger has written for the *New York Independent* an article intended to dissuade young men from entering the medical profession, and advocating the choice of the clerical profession instead. This article gives a very sombre view of the situation as far as young doctors are concerned, while telling some important truths which juveniles of both sexes contemplating medicine as a calling would do well to ponder. Dr. Munger (our reverend is a D. D.) says truly that, as a rule, professional men do not acquire wealth. The only hope that they can properly cherish is that of securing a living. Presupposing, then, intellectual fitness, moral earnestness, devotion to humanity, and all else that enters into a good minister or physician, the former is far surer of earning a living than the latter. In other words, the ministry is the better profession of the two, even from a worldly point of view. The medical profession seems to Dr. Munger (and he is right) to be overcrowded, and to such a degree that it no longer promises support to those who enter it. A few years ago, says the writer, there was in New York City one physician to 1500 of the population. According to the average ratio of the sick to the well — twenty in 1000 — this gave about thirty patients to each physician. But as a part of these were paupers, and a part went without treatment, or used quack medicines, the physician could rely on only fifteen to twenty paying patients provided they had been evenly distributed. To-day, however, there is in the United States one physician to every 650 persons; in the State of New York one to every 600; in New York City one to every 550. Thus the ratio of the sick to the well offers to the physician throughout the whole country only about ten possible patients, a part of whom go without treatment, and a part pay nothing. As a matter of fact the number of paying patients to each physician is from six to eight, but the older and more noted practitioners get the greater part of those, and so leave the new-comers with nothing to do, which is actually the case. Figures and experience go hand in hand in confirmation. "A young man," continues Dr. Munger, "who now enters the profession of medicine simply invokes poverty and want, and (what is worse) he defeats the end of his training by not exercising it. It may be noble and spirited to brave poverty, but nothing can justify a choice that necessitates idleness. There are, of course, exceptions springing out of wealth, family influence, good luck, and special talent, conditions on which few can count. The young physician, let him go where he will, — to New York or Dakota, — must contend with older and well established physicians for a living to be got from seven or eight sick people. His chances are about the same as picking up lost purses in the street, and his only hope is in praying, with Gil Blas, 'By the blessing of God may there be much sickness in this place!' It is unnecessary to picture the results of this overcrowding, — the degradation of mind and character that grows out of extreme poverty, the weary waiting, the heart-ache and heart-break, the defeat of purpose, the despair, the loss of skill, the dissipation sought to kill the sorrow, the unprofessional spirit and conduct induced by the struggle to gain a foot-hold. These common and increasing results are dangerous also to society. The hungry lawyer is to be feared, but Heaven save us from the hungry doctor! It is hard to understand why intelligent, forecasting young men should choose this profession in its present state."

The reverend writer has well presented the dark side of the picture. The swarms of young men (and young women) that are about to invade the numerous medical schools, north, south, east, west, with their arduous curriculum, might well pause before setting forth on this so perilous career. Are they prepared — impelled by an unconquerable love for this difficult and discouraging profession, perhaps also by a consciousness of eminent fitness — to meet the issue so well stated by Dr. Munger?

Such deliberation is especially proper on the part of those who contemplate exercising the profession as a livelihood, and who possess no resources on which to fall back for a series of years during the patient waiting for patrons.

There may be "room in the upper story," but there is no lack of eager, hungry, able competitors for the vacant space that is there.

Whether those who may draw back disheartened, having weighed well all the facts as above stated, shall accept Dr. Munger's advice and enter the ministry doubtless depends on certain important conditions which we need not insist upon here.

MEDICAL NOTES.

— Cholera, as was to be expected, is more active than last week at Toulon and Marseilles. Cases are also reported at Arles, Lyons, Paris, Madrid, and Vienna. A steamer had arrived in the Mersey from Marseilles, on board which two deaths from cholera occurred during the voyage.

— As possibly the previous notice in the JOURNAL may have escaped the attention of many, we would state that a list of physicians of the Suffolk District Medical Society who remain in Boston during the summer will be kept for the benefit of the public at the Medical Library, and those who have neglected to send their addresses, office hours, etc., can do so by addressing Dr. Edwin H. Brigham, Assistant Librarian, Medical Library, 19 Boylston Place.

— Dr. Jelly, of this city, who was assaulted and shot by an insane patient a few days ago, is, we are happy to learn, recovering, and it is hoped that no untoward results will permanently remain.

— The JOURNAL heartily sympathizes with every

effort to secure greater precision and elegance of style among writers upon medical subjects. It is doubtless true that, either from ignorance or carelessness, or both, many contributors to our journals present in their communications lamentable infractions of the rules of English syntax, and such errors will in spite of editorial care creep into the pages of the best periodicals. It cannot, however, but be regarded as a little unfortunate that one of our valued metropolitan contemporaries in an editorial article upon this subject uses the two following expressions: "No, not quite that bad," and "Some — almost every — writer speaks of a case," etc. If these phrases are intended to serve as "horrid examples," it might perhaps be as well to indicate that fact in some way.

— Mr. Benjamin Clarke has contributed an article to the *Pall Mall Gazette* on the subject of Penny Dinners for School Children. The experiment has been tried in London of distributing penny dinners to children attending elementary schools, and it has proved in the highest degree successful and satisfactory. The children largely availed themselves of the opportunity thus afforded them of obtaining a cheap and at the same time a good substantial dinner, which was distributed three times a week, with a daily average of 185. A total of 1663 dinners realized, at a penny each, £6 18*s.* 7*d.*, while the cost was £7 6*s.* 10*d.*, showing a loss of only 8*s.* 3*d.*, a loss which Mr. Clarke believes may be turned into a profit with more experience, but which he says need not deter any one from making the experiment. The experiment is likely to be largely tried both in London and the provinces.

— A correspondent of the *British Medical Journal* furnishes an interesting contribution to the much-discussed question as to the possibility of inducing anæsthesia during sleep. He writes: "Some years ago I was consulted by the parents of an excessively nervous girl, seven years of age, who was suffering from hypermetropia and double convergent squint. The agitation of the child and consequent distress of the parents at the idea of any surgical interference were so great that I thought it would be better to operate during sleep, and, after dismissing the patient with some reassuring remarks, arranged that this should be done the same night. Accordingly, about ten o'clock, when the child was fast asleep, I administered chloroform without disturbing her, and performed the operation on both eyes, replacing her in bed while still insensible. The anæsthetic sleep gradually merged into the natural sleep, which had never been broken; there was no vomiting, and the child did not wake until the following morning at the usual hour. There was no pain, and her alarm on finding that her eyeballs were bloodshot, when looking in the glass, was allayed by suggesting that she had caught cold. She made an excellent recovery. The deformity was quite removed, and she never suspected that she had undergone any operation at all."

— The Scyllæ and Charybdes between which the doctor has to steer his professional bark as he sails under the varying breezes of public opinion are thus feelingly pointed out by the *Hebrew Standard*: —

"If he visits a few of his patients when they are well, it is to get his dinner; and if he does not do so, it is because he cares more for the fleece than the flock. If he goes to synagogue regularly, it is because he has nothing else to do; if he does n't go, it is because he has no respect for the Sabbath nor religion. If he speaks reverently of Judaism, he is a hypocrite; if he does n't, he is a materialist. If he dresses neatly, he is proud; if he does not, he is wanting in self-respect. If his wife does not visit you, she is 'stuck up;' if she does, she is fishing for patients for her husband. If he has a good turnout, he is extravagant; if he uses a poor one on the score of economy, he is deficient in necessary pride. If he does not write a prescription for every trifling ailment, he is careless; if he does, 'he deluges one with medicine.' If he makes parties, it is to soft-soap the people to get their money; if he does not make them, he is afraid of a *cent.* If his horse is fat it is because he has nothing to do; if he is lean, it is because he is n't taken care of. If he drives fast, it is to make people believe that somebody is very sick; if he drives slowly, he has no interest in the welfare of his patients. If the patient recovers, it is owing to the good nursing he received; if he dies, 'the doctor did not understand his sickness.' If he talks much, 'we don't like a doctor to tell everything he knows,' or 'he is altogether too familiar;' if he does n't talk, '*we like to see a doctor sociable.*' If he says anything about politics, 'he had better let it alone;' if he does n't say anything about it, 'we like to see a man show his colors.' If he does not come immediately when sent for, 'he takes things too easy;' if he sends in his bill, 'he is in a terrible hurry for his money.' If he visits his patients every day, it is to run up a bill; if he does n't, it is unjustifiable negligence. If he orders the same medicine, it does no good; if he changes the prescription, he is in league with the druggist. If he uses any of the popular remedies of the day, it is to cater to the whims and prejudices of the people to fill his pockets; if he does n't use them, it is from professional selfishness. If he is in the habit of having frequent consultations, it is because he knows nothing; if he objects to having them, on the ground that he understands his own business, 'he is afraid of exposing his ignorance to his own superiors.' *If he gets pay for one half his services* he deserves to be canonized. Who would n't be an M. D.?"

— At the meeting of the American Medical Association held at Washington in May last an Amendment to Regulation II. was adopted which provides that membership in the Association shall be obtainable by any member of a State or county medical society recognized by the Association upon application indorsed by the president and secretary of said society, and shall be retained so long as he shall remain in good standing in his local society, and shall pay his annual dues to the Association.

— A homœopathic physician of Washington, Dr. Pearson by name, at a meeting of the Hahnemannian Society of Washington, according to a report in a journal of that complexion, styled homœopathic physi-

cians who do not follow the Hahnemannian system of therapeutics "half-breeds." In his reply to a toast given at the banquet given the Hahnemannian Society he said the charge is false that homœopathists give as crude doses as other physicians and send their prescriptions to druggists to be filled, and added: "Any physician who does this is a hypocrite, and a disgrace to the name of homœopathy. They (*i. e.*, homœopaths?) repudiate and discard such a prescriber, and while they could tolerate an allopathic physician who honestly practiced what he preached they felt nothing but contempt for the mongrel or half-breed who would 'steal the livery of heaven to serve the devil in.'" The aptness of this quotation is quite delicious.

— A man having fallen in an epileptic fit lately, in the region of the Five Points, three policemen, we learn from a contemporary, bound him with cords to an awning-post, gagged him, and stood over him with drawn clubs ready to administer promptly to any symptoms of hydrophobia that he might show on recovering consciousness, they having been told that the man had been bitten by a dog.

— "Doctor, I want you to do something for me. My nerves are shattered completely. I am not able to eat anything, and I sleep very little at night. What would you advise me to do?"

"What has brought about this condition?"

"Drinking too much, I'm afraid."

"Well, I would advise you to give up drinking."

"H'm, that idea never occurred to me. What's your charge for the advice?"

"Nothing."

"Nothing? I'm much obliged to you, doctor. Let's go and take something." — *New York Sun.*

— A candidate for license to practice medicine in North Carolina (and by the way an unsuccessful candidate) when asked "Who discovered vaccination?" replied "Virchcow." — *N. C. Med. Jour.*

NEW YORK.

— During the week ending July 12th the summer corps of sanitary inspectors visited 4504 houses and 24,099 families; 811 cases of sickness were found, and of these 365, nearly all of which occurred in children, were of diarrhœal trouble; 70 cases of contagious disease were discovered. The following special instructions have been issued to the corps by the sanitary superintendent: "All cases of contagious disease discovered, whether the patients are under treatment or not, are to be immediately reported to this bureau, giving name, age, and residence of the patient. The duties of this service are not limited to tenement-houses, but extend to all dwellings occupied by the poor, and in view of the possible advent of cholera special attention should be paid to shanty neighborhoods in unsewered portions of the city, where excreta are deposited in shallow vaults or upon the surface of the ground, and where the water supply is from springs or surface wells. All such places which require disinfection must be at once reported to this bureau."

— James Reilly, a performer with snakes, was bitten on the hand by a large rattlesnake over five feet in length, at High Bridge, in the upper part of the city, on the 14th of July, and died the following day at the Ninety-ninth Street Hospital, to which he was taken in an ambulance shortly after the receipt of the injury. As soon as he was bitten the man had applied his lips to the wound and exerted all the suction of which he was capable, and had then partaken very freely of whiskey. At the hospital he was treated mainly with hypodermic injections of ammonia and whiskey, but it does not appear that even at first a ligature was applied about the arm or that the question of amputation, which is frequently resorted to under similar circumstances by surgeons in India, was entertained. On the 16th Dr. Messonier, deputy coroner, made the autopsy in the presence of a number of physicians at the morgue. He found more or less congestion of all the tissues of the right arm (the hand of which had been bitten) and of the right side. No part of the left side was congested, but all the thoracic and abdominal viscera were. The heart was pale and flabby, and the blood in it, as well as in the arteries and veins, was perfectly fluid. The cause of death, on the certificate made out by Dr. Messonier, was stated to be "Syncope from septicæmic gases entering the right auricle of the heart. Septicæmia caused by a bite on the right hand from a poisonous rattlesnake."

Miscellany.

THE SEEN AND THE UNSEEN.

A SONNET BY THE LATE DR. R. D. JOYCE.

THERE was recently put into our hands a sonnet by the late Dr. Robert Dwyer Joyce, written by him on the fly-leaf of a copy of his poems which he was about to present to one of his friends. The sonnet was impromptu, and not intended for publication, but it is a pleasure to give publicity to so charming a bit of verse. It presents a pleasing picture, and undoubtedly a true one, of the mental life of the gifted but erratic author, who was accustomed to compose his poems as he walked the streets. Exactly as it stands, the sonnet applies probably to few others of the profession, for few physicians can claim familiarity with the glorious hill of poesy, but we believe that the individuals among us who lead two lives are common enough to make the little sonnet something more than poetic phrensy. Most children are known to have a world of their own, the product of their own brains from material furnished in part by their own imagination, in part by the nursery classics, in which they take refuge when the real world proves unkind, or time hangs heavy on their hands, and something of the kind is true of a smaller number of grown-up children. Unfortunately their unseen world does not always take on so pleasant a form as the poet's magic town. It is too often the country of the Might Have Been, whose inhabitants spend their time in calculating how far they would have journeyed had they never dallied by the way, and whose willows and myrtles have rooted out the asphodel.

We can but envy the happy disposition which could lift the soul above earthly troubles, and leave vain regrets for duller mortals.

SONNET.

I live two lives: one full of all unrest,
One full of heavenly joys of heart and brain.
In one I walk around mid grief and pain,
And hear the deep signs of the saddest breast
And groanings of the stricken ones, and see
The sad pale face of death and misery.
The poor man's load of grief, the rich man's frown,
And the fell leer of sin, till I am sad: —

In one I wander through a magic town,
Paven with pearls and in sweet garlands clad
From the bright meads of asphodel that crown
The glorious Hill of poesy, — the glad,
The green, delightful hill whose cliffs of gold
Each day with eyes of rapture I behold.

Robert Dwyer Joyce.

THE RISKS OF CORROSIVE SUBLIMATE INJECTIONS.

The unfavorable cases are beginning to be reported of the use of corrosive sublimate, as what we know of idiosyncrasy leads us to expect in the use of any powerful remedy. In *Schmidt's Jahrbücher* (Bd. 202, No. 4) some such instances are related. Professor Stadfeldt, of Copenhagen, while admitting its efficacy in most cases, is yet evidently somewhat afraid of it, especially as intrusted to midwives during labor. In the puerperal state he used it with excellent results in six consecutive cases, but in the seventh the effect was as follows: The patient, a twenty-three year old primipara, had a retained placenta, which required artificial removal. Uterus and vagina were at once washed out with carbolic solution. Four days after there was a chill, with temperature of 39° C. The next day a solution (1–1500) of corrosive sublimate was injected. After about 300 to 400 grammes of the solution had run out the patient suddenly complained of headache and difficult breathing. Her replies were somewhat uncertain, but consciousness was undisturbed. Some pains came on in the hypogastrium; the whole lower abdomen was tender, but not swollen. After a time a profuse sweating came on, and the pains ceased. There were heaviness, giddiness; stools thin; tenesmus; urine highly albuminous; no fever; temperature subnormal. In course of the next day the most important symptoms were vomiting, thin stools, with tenesmus, great thirst, and headache. The fifth day after the use of the injection the urine stopped, the consciousness became clouded, and the patient died quietly on the next.

Of course the cause of death was not at once certain, but an autopsy showed no peritonitis. Numerous ulcerations were found in the large intestine. The kidneys were much altered. Mercury could be detected in no organ. Stadfeldt considered it a case of death from mercurial poisoning.

Other instances are also cited. We make room for one other. A woman was operated upon for prolapsus of the vagina and rectum. During the operation, which lasted one hour and a half, the flaps were washed from time to time with a 1–1000 solution of sublimate. The next day the vagina and anus were washed with the same solution, which was also injected into the rectum. On the sixth day the patient complained of great pain in the mouth. The gums were seen to be inflamed. There was much salivation. The use of the sublimate was stopped, and vigorous treatment directed to the mouth, after which the symptoms vanished in a few days.

THE VALUE OF SINGLE SYMPTOMS IN THE DIAGNOSIS OF MANY DISEASES OF CHILDHOOD.

The *Medical and Surgical Reporter*, July 12th, reproduces editorially the substance of a paper by Dr. L. M. Politzer, for many years Director of the Public Hospital for Children in Vienna, which was recently published in *Deutsche Med. Zeit.*, May 19, 1884. The symptoms principally considered are the following: —

(1.) *If the cry of children has a decided nasal sound*, we should always look for a retro-pharyngeal abscess. Whenever the cry of a child has this peculiar nasal or guttural sound, we should never omit touching the posterior wall of the pharynx with our finger; if the abscess is present we feel the tense, fluctuating swelling so characteristic of retro-pharyngeal abscess.

(2.) *A noisy expiration, which is greatly prolonged (ten to fifteen times), while inspiration is normal, and no other disturbance of breathing, no dyspnœa whatever exists*, is a sure sign of chorea major, and the same can be said of a greatly prolonged, very loud, and forcible expiration, sounding like bellowing. This symptom of bellowing (brüllend) expiration has a typical character; it may happen for many weeks daily at one and the same hour, recurring every seven to ten seconds, and it usually consists of a single prolonged and forced expiration, or of a single expiratory roar. For months sometimes this symptom is the only sign of chorea major. It is easily cured by large doses of quinine, but is very prone to relapse and to be accompanied by other symptoms of chorea major.

(3.) *The symptom of high-thoracic, continually sighing inspiration* indicates the beginning of debility and paralysis of the heart. Ere cyanosis or paleness of the face, a weak, thread-like pulse, and coldness of the face, of the nose, and of the extremities develop themselves, this symptom makes its appearance. Contrary to stenotic respiration, as observed in croup, pneumonia, and œdema of the glottis, this sighing inspiration is not characterized by forced contractions of the diaphragm, and is not of abnormal type, but is accompanied by a laborious rise and fall of the thorax and jugulum, and instead of a stenotic noise by continuous sighing and moaning. No matter how the paralysis of the heart may be produced, — whether by so-called heart-poisons, as quinine, salicylic acid, pilocarpin, and digitalis, or otherwise, the symptom just described is pathognomonic of the disease, and whenever met with precautionary measures to combat the threatening palsy of the heart should be at once resorted to.

In some cases of acute fatty degeneration of the heart the same symptom has been observed.

(4.) *Expiration, decidedly diaphragmatic, and accompanied by a whistling sound of high pitch*, denotes bronchial asthma. A similar symptom is also met with in croup; but here it is associated with stenotic, forcible inspiration. The same is observed in capillary bronchitis; but the noisy breathing through the nose, the rapid development of pulmonary emphysema, the sud-

den appearance and disappearance of intense dyspnœa, and the fact of the latter and the whistling remitting during deep sleep, will prevent error.

(5.) *The existence of noticeable pauses between the end of each expiration and the beginning of the next inspiration* indicates severe catarrh of the larynx, and proves the absence of croup.

In consequence of the enormous aspiration of air in croup, inspiration and expiration follow each other immediately, while in laryngeal catarrh a pause takes place between the two acts, as the physician can convince himself by bringing his ear near the mouth of the patient, or by carefully watching the diaphragm and the jugulum, both of which are at rest during a pause.

(6.) *So-called stridulous expiration*, if present at birth and continuing day and night with rare interruptions of ten or fifteen minutes' duration, and usually considered by anxious mothers and the uninitiated a dangerous and ominous symptom, has neither diagnostic nor any other importance, being perfectly innocent, and generally ceasing of its own account after the lapse of a few months.

Then there are certain symptoms enabling us early to recognize various *diseases of the brain* in children: —

(1.) *A remarkable drowsiness, not accompanied by fever or any other symptom, and continuing for a longer time* (*one to three days*), often precedes basilar meningitis.

Vomiting, fixed pain in the head, even a slow, irregular pulse, have not the same great significance as this sleepiness, as they may also happen in other maladies. Certainly, stress must be laid upon the absence of fever, for many infectious diseases begin in children with a peculiar drowsiness, always associated, however, with more or less high fever.

(2.) *Prominent anterior fontanelle*, if decidedly reaching above the level of the surrounding parts, and if tense and of such a resistance as not to yield under pressure, proves the presence of an exudation within the cranium, or an increase of the contents of the latter, and is met with in purulent meningitis of the convexity, in cerebro-spinal meningitis of the epidemic variety, in acute, essential, and chronic hydrocephalus (here tense, but not necessarily very prominent), in great tumors, in echinococci, in acute œdema of the brain, and in intermeningeal apoplexy. In simple congestion, in acute hyperæmia of the brain, the anterior fontanelle always is soft and depressible. If the fontanelle is very prominent, almost cuneated and unyielding, without the least trace of pulsation, the diagnosis of apoplexy of the new-born, and a large intermeningeal extravasation of blood, can be made with certainty.

(3.) *Remarkably slow motion and long fixation of the bulbi with a vague look into vacancy, accompanied by a peculiar, slow opening and closing of the eyelids*, is a sign of beginning basilar meningitis.

Next, *peculiarities of the cry* of children aid us in the diagnosis.

(1.) *Violent, loud, penetrating crying, lasting two or three minutes, accompanied by great anxiety, as expressed in the face, and setting in almost typically, one to one and a half hours after the child has fallen asleep*, is a symptom of nightmare, and easily cured by quinine, which, in the dose of five to eight grains, should be administered one or two hours before retiring.

(2.) *Periodical crying, lasting five to ten minutes, and happening several times in the day, but occasionally only at night*, draws the attention to spasm of the bladder, if colic or dyspepsia is not present, and is cured by an emulsion of lycopodium, with or without belladonna.

(3.) *Frequent crying during defecation, dread of the act, and decided opposition of the child to going to stool*, indicate the existence of fissure of the anus. Constipation should be avoided in such cases, and zinc-ointment, with belladonna, locally applied.

(4.) *Violent, very painful, and nearly continuous crying, with restless throwing of the head from side to side* on the pillow, and frequent grasping of the head by the hands, are generally indicative of otalgia and otitis media and externa.

(5.) *Crying, lasting days and weeks, greatly increased on touching or moving the extremities*, accompanied by continuous, enormous perspiration and fever, denotes the presence of acute general rachitis, while the same symptom, without the sweating, but with decided emaciation, proves the existence of hereditary syphilis, and that the case is hopeless.

Of a great number of other symptoms we will mention but the following, as they are of more common occurrence and of greater importance.

When children are remarkably weak and little inclined to moving about after apparently innocent complaints of very short duration, *spinal infantile paralysis* may be expected. The least disturbance of hearing after acute diseases must be carefully inquired into, as it might be caused by *circumscribed meningitis* at the base of the fourth ventricle. Depression of psychical activity in small children after grave infectious diseases frequently forms the commencement of *acquired idiocy*; here strychnine has been proven by experience an invaluable remedy. Ossification of the bones of the cranium postponed longer than normal denotes beginning *rachitis*. An anxious, stiff action in walking, sitting, rising, etc., and pain expressed in the face of children, who do not yet walk, when they are lifted or laid down, are met with in the commencement of *spondylitis*. When children with a very large, closed cranium for weeks vomit everything they eat, we have the proof that acute hydrocephalus is being added to the former chronic disease.

OVULATION, COITION, AND IMPREGNATION.

DR. H. J. GARRIGUES furnishes to the *Journal of Obstetrics* (May) an abstract from an article by Dr. P. L. Panum, Professor of Physiology at the University of Copenhagen, in the *Nordiskt Med. Archiv*, vol. xiv., No. 29, which is a contribution to our knowledge of the relation between menstruation and ovulation and the vitality of the spermatozoids in the female genital tract. He says himself that the whole number of exactly observed cases are yet much too small to determine whether the impregnated ovum, as a rule, was detached at the last menstruation or at the time when the next menstruation should have occurred; but in his case he proves that the latter condition obtained.

A married lady in the higher walks of society, forty-three years old, had borne seven children, the last two and one half years ago, and had had two abortions in the third month, one and two years before the present one. Since then, she had had no sexual intercourse except

once, namely, on the 10th of April, 1882. The last menstruation had been present from the 3d to the 5th of the same month. On the 8th of June she had again an abortion. Menstruation had been regular up to April, except that it had come three times with an interval of only fourteen days, the last time on April the 3d.

Dr. Panum argues that during the first two or three months the development of the fœtus is so regular that every week has its own signs. That, in the present case, it corresponded to the fifth week. The antero-posterior diameter of the head was four millimetres. By the development of a median and two lateral frontal processes the nasal fossæ had been transformed into grooved canals. The median frontal process showed in the centre a small shallow notch. Under the eye appeared on either side the upper maxillary process, and it rested on the lower edge of the lateral frontal process without reaching the median frontal process. The inferior maxillary processes protruded further than the superior maxillary processes, and touched one another in the median line. The oral fissure, starting from the oral orifice under the median frontal process, extended between the superior and inferior maxillary process below the whole of the eye. The fissure-shaped foundation of the outer ear had an entirely horizontal position. Otherwise, the visceral clefts were closed; but as remnants of the three anterior visceral arches, three corresponding rounded folds were still visible on the neck. The caudal extremity was distinct, and rolled inward with a sharp curvature. The extremities showed the beginning bend of the knee and the elbow. The distance from the vertex to the caudal extremity was eleven millimetres. The heart and the large arteries contained bright-colored blood, and the whole fœtus was so well preserved that there could be no doubt that it had lived until near the time the abortion occurred.

It is evident from the period of development of the fœtus that it could not have been formed in an ovum detached at the last menstruation, which occurred more than two months before the abortion took place, but that it must be referred to the next monthly ovulation, at which no flow appeared, and which, according to the development of the fœtus, must have taken place in the beginning of May, four weeks after the last menstrual discharge, and about three weeks after the single connection. During all this time the semen must have been preserved in the female genitals in such a condition as to retain its fertilizing power. It is probably kept in the upper end of the Fallopian tube, which is developed so as to form a *receptaculum seminis*.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 12, 1884.

Deaths reported 3608 (no reports from Buffalo and Milwaukee): under five years of age, 2121; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, diarrhœal diseases, and fevers) 1394, diarrhœal diseases 1076, consumption 374, lung diseases 207, diphtheria and croup 72, measles 63, whooping-cough 50, scarlet fever 43, typhoid fever 38, malarial fevers 35, cerebro-spinal meningitis 11, puerperal fever eight, small-pox four, erysipelas four. From *scarlet fever*, New York 14, Chicago six, Philadelphia five, Brooklyn and St. Louis four each, Boston, Cincinnati, and Pittsburg two each, New Orleans, District of Columbia, Lowell, and Somerville, one each. From *typhoid fever*, Philadelphia nine, St. Louis six, New York and Chicago four each, Brooklyn, Boston, Baltimore, and Cincinnati two each, District of Columbia, Pittsburg, Providence, Nashville, Charleston, Lowell, and Newton one each. From *malarial fevers*, Brooklyn nine, New Orleans eight, St. Louis seven, New York five, Baltimore and Charleston two each, Philadelphia and Nashville one each. From *cerebro-spinal meningitis*, New York, Chicago, Cincinnati, Worcester, and Fall River two each, Brockton one. From *puerperal fever*, Fall River two, Brooklyn, Chicago, Boston, St. Louis, and New Orleans one each. From *small-pox*, New Orleans three, Philadelphia one. From *erysipelas*, New York and Philadelphia two each.

Cases reported in Boston: scarlet fever 47, typhoid fever 25, and diphtheria 12.

In 107 cities and towns of Massachusetts, with an estimated population of 1,385,681 (estimated population of the State 1,955,104), the total death-rate for the week was 17.88 against 15.35 and 15.41 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending June 30th, the death-rate was 19.2. Deaths reported 3230: acute diseases of the respiratory organs (London) 218, measles 144, whooping-cough 122, diarrhœa 90, scarlet fever 50, fevers 42, diphtheria 27, small-pox (London 29, Liverpool five, Sunderland two, Manchester, Sheffield, and Cardiff one each) 39. The death-rates ranged from 11.5 in Brighton to 26.1 in Liverpool; Birkenhead 17.2; Birmingham 19.2; Blackburn 23.6; Leeds 20.1; Leicester 16.5; London 19.1; Manchester 22.1; Nottingham 20.1; Sheffield 16.7; Sunderland 23.3. In Edinburgh 15.7; Glasgow 23.3; Dublin 28.2.

For the week ending June 21st, in the Swiss towns, there were 29 deaths from consumption, lung diseases 15, diarrhœal diseases 12, typhoid fever nine, diphtheria and croup four, scarlet fever two, whooping-cough one. The death-rates were, at Geneva 17.3; Zurich 3.9; Basle 21.4; Berne 10.1.

For the week ending June 28th, in the Swiss towns, there were 29 deaths from consumption, typhoid fever 19, diarrhœal diseases 14, lung diseases 13, diphtheria and croup three, whooping-cough two. The death-rates were, at Geneva 13.2; Zurich 11.8; Basle 20.1; Berne 12.2.

The meteorological record for the week ending July 12th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JULY 12, 1884, TO JULY 18, 1884.

CLEMENTS, B. A., major and surgeon. Also directed to relieve Surgeon J. P. Wright of his duties as Acting Medical Director, Department of the Missouri. Paragraph 1, S. O. 138, headquarters Department of Missouri, July 8, 1884.

MCELDERRY, HENRY, captain and assistant surgeon. From Department of the Platte to Department of the East. Paragraph 12, S. O. 165, A. G. O., July 16, 1884.

EWEN, CLARENCE, captain and assistant surgeon. Assigned to duty as post surgeon, Fort Sidney, Neb. Paragraph 8, S. O. 58, headquarters Department of Platte, July 11, 1884.

ELBREY, F. W., captain and assistant surgeon. Leave of absence still further extended six months on surgeon's certificate of disability. Paragraph 6, S. O. 161, A. G. O., July 12, 1884.

WAKEMAN, WILLIAM J., first lieutenant and assistant surgeon. Relieved from duty at Fort D. A. Russell, Wyo., and assigned to duty as post surgeon, Fort Washakie, Wyo., relieving Assistant Surgeon Norton Strong. Paragraph 9, S. O. 58, headquarters Department of Platte, July 11, 1884.

APPOINTMENT.

CHARLES B. EWING to be assistant surgeon, with the rank of first lieutenant, July 5, 1884, vice Middleton, promoted. Memo., A. G. O., July 14, 1884.

LIST OF OFFICIAL CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING JULY 19, 1884.

GIHON, A. L., medical director, ordered as member of Board of Inspection.

PERSONS, R. C., passed assistant surgeon, ordered to U. S. S. Saratoga.

SEIGFRIED, C. A., passed assistant surgeon, detached from U. S. S. Saratoga, ordered to Naval Hospital, Brooklyn.

SAYRE, T. S., assistant surgeon, ordered to U. S. S. Independence.

BOOKS AND PAMPHLETS RECEIVED. — Notes on the Opium Habit. By Asa P. Meylert, M. D. Second Edition. New York: G. P. Putnam's Sons. 1884.

The Objects of Dermatological Classification, with Especial Reference to Auspitz's System. By Edw. Bennet Bronson, M. D. (Reprint.) New York: William Wood & Co.

Disease in Cattle, Kansas and Illinois. Letter from the Secretary of the Treasury. Public Document.

Quarterly Report of the Chief of the Bureau of Statistics, Treasury Department, Relative to the Imports, Exports, Immigration, and Navigation of the United States for the Three Months ending September 30, 1883. No. 1.

Same. No. 2. For the Three Months ended December 31, 1883.

Address.

THE PHYSICIAN A POPULAR EDUCATOR.[1]

THE ANNUAL DISCOURSE BEFORE THE MASSACHUSETTS MEDICAL SOCIETY, JUNE 11, 1884.

BY JOHN CROWELL, M. D., OF HAVERHILL.

THE attitude of the public in regard to the management of *Contagious* and *Infectious Diseases* is often at fault, and it is here where the timely interference of the physician is of vital moment.

Notwithstanding the rules and restrictions of Boards of Health, the grossest carelessness prevails, and exposure to diseases accounted contagious is encouraged by this easy-going negligence. Take, for instance, that much dreaded malady, diphtheria. Dr. Elisha Harris, of New York, in his report of the investigations made by him of the epidemic that occurred in Vermont in 1879, makes the following practical suggestions: —

"No other disease in our Northern States has been more generally regarded as unpreventable, and none more capricious and fatally obstinate in its mode of prevalence, than diphtheria. Its apparently, and very probably, sporadic origin in numerous instances; its invasion of the most salubrious as well as the most insalubrious quarters; its variable malignancy, and its rapid fatality in numerous cases wherever it prevails, have furnished ample occasions for the unsettled opinions and sanitary regulations which prevail in regard to this destructive malady. Medical men no longer reject the conclusion which experience has taught concerning the personally contagious attribute of diphtheria; but as this attribute is variable in its intensity in different cases and on different occasions, apparently, sanitary precautions and regulations adopted to extinguish or wholly control the virus of this disease are only occasionally applied and enforced."[2]

This condition of things in relation to this disease, so carefully and so cautiously stated by high authority, has resulted in a deplorable looseness among all classes. Because the contagion of diphtheria differs from that of other well-known diseases in the character of inception and development, the public mind becomes indifferent to the suggestions of sanitary authorities, and in many localities we find an almost open defiance to all precautions. There is often no system of isolation during the prevalence of an epidemic; there is gross neglect in the use of such disinfectants as are sanctioned by the best authorities; there is but little attention paid to the cleansing of houses, bedding, and clothing; and, worse than all, there is a reckless disregard for the safety of the living in the disposal of the bodies of those who have fallen victims of the disease. Numerous instances could be cited where public funerals have been held, and the body of the dead child, bedecked with floral emblems in an open casket, has been followed to the grave by a procession of school children. This dangerous expression of sentiment finds encouragement too often by clergymen, teachers, and even parents, especially when the victim of the malady is a favorite child and very generally beloved. People need wholesome rules from the physician in the conduct of this disease, and, in the absence of local sanitary authority, his word must be potent in its explicitness, and with a savor of authority in its practical application.

There is another question growing out of contagious diseases that is engrossing no little attention. I refer to *Vaccination*.

The public mind is somewhat divided as to the efficacy of vaccination as a preventive or modifier of small-pox, and also as to the danger attending the operation in transmitting certain loathsome diseases, more to be dreaded than the pest against which the prophylactic treatment is directed. In every little community, in every rural school district, there will be found men who will rebel at any attempt at compulsory vaccination, and oftentimes family feuds and bitter personal strife are the disagreeable results of an order for a general protection during a visitation of small-pox. Certain newspaper writers keep up the controversy, and sometimes a member of our profession widens the breach by the authority of his assertions, or by the sophistry that lurks in isolated statistics, and in the glamour of semi-professional nomenclature.

We frankly admit that the process of vaccination has been subjected to abuse, and that grave evils have resulted from the carelessness of the operator; for vaccination, like every other operation on the human body, demands care and skill in its performance. The evils of pyæmia and syphilis, which have ensued in certain cases, have been due either to the use of a foul lancet, or of lymph, which, from remaining too long in the vesicle, had begun to decay, or from employing lymph mixed with the blood of a diseased subject. The evils of vaccination, then, can be easily avoided, and the remedies are very simple, — a clean lancet, and pure lymph unmixed with blood or any other secretion. And since such ample facilities are afforded to procure virus from the cow, there need be no fear on the ground of vaccino-syphilitic inoculation.

And yet compulsory vaccination meets with stout opposition at home and abroad. The law in England demands that all children shall be vaccinated within four calendar months of birth; but this provision is so imperfectly fulfilled that, according to official reports, "the public defences against small-pox are in great part insufficient and delusive."[3] During the last session of the British Parliament the whole matter of compulsory vaccination came before the House of Commons by a resolution introduced by Mr. P. A. Taylor, member for Leicester, as follows: "That in the opinion of this house it is inexpedient and unjust to enforce vaccination, under penalties, upon those who regard it as unadvisable and dangerous." This resolution was supported by a speech of great vehemence, in which the whole system was denounced not only as dangerous, but utterly useless, and, without taking the trouble to produce facts, Mr. Taylor dogmatically asserted that as "a factor in national mortality small-pox is nowhere at all."

It was for Sir Lyon Playfair to reply to these assertions, which he did by a masterly array of facts, too convincing to admit of controversy, and which are worthy of reproduction. A military surgeon testified before the committee of 1871 that of over one hundred and fifty thousand soldiers vaccinated, not one instance was on record of the transmission of disease by the operation. And of the 17,000,000 children vaccinated within the last thirty years, Sir Lyon challenged any one to produce four authentic cases that had been poisoned by a syphilitic taint.

And in further elucidation of his position he pre-

[1] Concluded from page 76.

[2] Annual Report of the National Board of Health, page 291.

[3] Fifth Report of Medical Officer of British Privy Council, page 6.

sented a concise array of facts showing the beneficial results of vaccination. These facts are so succinct that they are of practical value in meeting popular errors upon this vital topic.

In forty years after the introduction of vaccination into England the death-rate from small-pox had fallen from 3000 per million to 600 per million, and after gratuitous vaccination had been ordered in 1841 the average mortality was brought down in thirteen years to 305 per million.

Again, when vaccination was made compulsory, in 1871, the ratio of fatality was reduced to 223 per million; while in Scotland, in 1882, the rate was only six per million. Remarkable results are also observed in the late Franco-Prussian war. The year before the war 40,000 French soldiers and 216,426 Prussian soldiers were re-vaccinated. There was not, however, time to re-vaccinate a large number of recruits who entered the French army from Brittany, where small-pox was prevalent. And the physician-general of the French army, Dr. Leon Colin, records, "That the different armies, raised in haste and placed in the field without time for re-vaccination, were exposed both at their places of gathering and in their marches to the attack of the epidemic. The result was, that while 23,499 French soldiers died of small-pox, the mortality among the Germans did not exceed 263 deaths."

In London the deaths of the protected and unprotected are relatively 90 and 3350 per million, while in America the deaths of the unvaccinated are fifty per cent. in Boston, sixty-four per cent. in Philadelphia, and fifty-four per cent. in Montreal, and among the vaccinated the mortality is from fifteen to seventeen per cent.

At the conclusion of his argument, Dr. Playfair moved the following amendment to the resolution: "That in the opinion of this house, the practice of vaccination has greatly lessened the mortality from small-pox, and that laws relating to it, with such modifications as experience may suggest, are necessary for the prevention and mitigation of this fatal and mutilative disease."[1]

And this resolution was sustained by the remarkable vote, three hundred and two, while the anti-vaccination party mustered only sixteen votes.

It would seem, then, to be an easy matter to convince even the most skeptical that vaccination is a necessary means of defense against a terrible disease, and with Jaques, in As You Like It, the physician can confidently exclaim, with reference to this scourge of mankind: —

> "Give me leave
> To speak my mind, and I will, through and through,
> Cleanse the foul body of the infected world,
> If they will patiently receive my medicine!"

What better service can the profession render to the community than to assert a well-defined polity against *Superstition*, *Empiricism*, and *Quackery*?

The medical world has been more or less under the sway of superstition from the time of the early Egyptians to the latter part of this nineteenth century. During the highest period of Grecian civilization the disciples of Æsculapius depended upon feasts, fastings, and religious ceremonies for the cure of disease. The Romans combated the plague by incantations to the gods in the temple of Jove. The early Christian church believed that the power to cure disease lay wholly with the bishops and elders by the use of a miraculous power, independent of remedial agents. In later times kings and queens of England and France claimed the power of curing disease by the laying on of hands. Queen Anne touched the king's evil of Dr. Johnson, who was brought by his mother in his infancy for royal treatment by recommendation of a distinguished physician of Lichfield. And this kingly prerogative which prevailed through the Stuart dynasty was afterward assumed by those of less note, who passed through all the stages of wonder-working power possible to a diseased imagination.

Of the multiplied forms of superstition that have come down to us as a legacy, some are too trifling and harmless to deserve attention. Let the Dr. Johnsons remain happy by always putting forward the left foot on entering a room, and allow the college student the luxury of wearing a nutmeg strung around his neck as a talisman against disease. But when the foolish myths of an ignorant age are perpetuated and made to environ the pathway of a pregnant woman, and subject her footsteps to a succession of pitfalls and spring-guns; when the life of a young mother is made wretched by the old wives' fables of the dangers attending every period of lactation and dentition, it is well to challenge these miserable maxims and "call a halt."

Quackery does not always appear in the *rôle* of a mendicant who practices his base arts upon the unwary and the ignorant. It does not always flaunt its filthy rags and display the tawdry show of its stock-in-trade to the gaping crowds in the streets. It has other artifices and other devotees. It sometimes assumes the air of a gentleman and rides in a gilded coupé. It finds too easy access to the home of affluence and fashion, and the doors of the library and the boudoir open to its persuasive knock. It can adapt itself to all moods, and patiently lies in wait for the weakness and duplicity of suffering humanity. It is in such lurking and subtle form and garb that this foe to science and to humanity is most to be feared. And do we not sometimes find it seeking refuge behind the protecting seal of a piece of parchment?

It is a grim satire upon the pride and glory of medical science that the confidence of the great public in the power of specifics, as curative agents, remains as strong as in the former days of alchemy and astrology. Perkins's tractors and Bishop Berkeley's tar-water are perpetuated in the long list of patent nostrums that come in like a flood and threaten to overwhelm the land. Colossal fortunes are amassed from the sale of vile concoctions, whose virtues are set forth with all the glaring allurements of cheap art, and the convincing logic of those grateful people who, in turgid rhetoric, tell the suffering public of their ready relief from maladies which "regular physicians" had tried in vain to cure. What a piece of patchwork is man, with his garniture of liver pads, lung protectors, electrical belts and jackets! How is he guarded from all pulmonary ailments by alternate trials of stuffing and starving! How is he led captive by the invitations and warnings that confront him in painted characters upon every available rail-fence or rocky cliff in the land! How does the poor long-suffering stomach run the peptonized gauntlet, and barely escape destruction in the dreadful ordeal! And will not mercy cry out in pity for the helpless babies in their struggles with many of the preparations of artificial food? Denied

[1] From Parliamentary Report published in the Boston Daily Advertiser, July 4, 1883.

the nourishment that nature so bounteously pours out, these poor victims of mercenary greed are stuffed with an ever-varying round of compounds that vie with each other only in the differing grades of worthlessness.

Empiricism not unfrequently appears in the itinerant lecturer, who, with an airy grace, exhibits his credentials, and unfolds his manikins and his skeletons to the applauding public. And, having prepared the way by a generous course of free lectures, he plies his specialty with lucrative success, and then leaves his victims to wonder why they are not cured, while he is "over hills and far away" with his ill-gotten gains. And before the old-fashioned family doctor has finished making repairs on mutilated eyes and scarified organs of generation, or has found time to remove the pessaries and supporters, and liver pads and electric belts, the annual visitant again appears, and finds new victims to his devices with a generous patronage from his old dupes.

Massachusetts is far behind many of her sister States in the enactment of laws regulating the practice of medicine. While nearly every other State and Territory have done something, more or less effective, in this direction, our own State is unprotected, and quackery in every form is practically unhindered in its imposition upon the public.

The State of Illinois has done noble service to science and to humanity by empowering the State Board of Health to regulate the practice of medicine, and this has been done so wisely and so efficiently that quackery and empiricism find but feeble foot-hold within its jurisdiction. From the admirable and exhaustive report recently prepared by Dr. John H. Rauch, the able secretary of the Board of Illinois, we gather valuable information upon the whole subject of "Medical Education, and the Regulation of the Practice of Medicine in the United States and Canada." In the long list of States that have enacted laws of various degrees of force and effectiveness the name of Massachusetts does not appear, while those States possessing *good* laws are North Carolina, Alabama, West Virginia, Illinois, Missouri, Minnesota, New Mexico, Wyoming Territory, Mississippi, and Louisiana.

The Illinois Board of Health did important service in the exposure, in November, 1882, of the fraudulent "Bellevue Medical College of Massachusetts," which issued medical diplomas under the protection of a law relating to "Manufacturing and other Corporations." And the officers of this "bogus" college contended that they had a legal right to issue diplomas and confer degrees without any restriction on account of study or professional attainments. The United States Commissioner, before whom the trial was had, held this plea to be valid, and dismissed the case with the following remarks: "The State has authorized this college to issue degrees, and it has been done according to legal right. The law makes the Faculty of the College the sole judges of eligibility of applicants for diplomas. If the Faculty choose to issue degrees to incompetent persons *the laws of Massachusetts authorize it.*"

Such an outrageous possibility, under a law of Massachusetts, has been canceled, and the State saved from further disgrace in this direction, by the passage, June, 1883, of an act forbidding any corporation organized under the law referred to from "conferring medical degrees or issuing diplomas, unless specially authorized by the Legislature so to do."

Why should Massachusetts lag so far behind other States in the enactment of laws so wise, just, and humane? Laws not primarily intended to protect the medical profession, but to stand between the public and the horde of vampires that feed upon the life blood of their ignorant, superstitious, and deluded victims.

Is it not the duty of the members of our profession to educate the popular mind into a right appreciation of this vital question, and so to enlighten our legislators as to induce them to enact laws that shall redeem the good old Bay State from the contumely of fostering, by her legislation, the basest kind of frauds upon her citizens?[1]

Such, then, Mr. President and Fellows, are some of the methods by which the physician can render service to the public. It may be unrequited service; it may be called drudgery, but it is the drudgery that comes from ministration and sacrifice. It is the service essentially belonging to the highest ideal of the medical profession; a profession which makes the most profound problems of scientific research subservient to the wants of suffering humanity; whose noblest teachers and specialists are found wherever misfortune and woe have sown the seeds of disease.

It is a service scattered broadcast over the land. The same in the country doctor who toils among the hills of Berkshire, or along the sandy reaches of the Cape, as in the city practitioner who threads his way, not only among the homes of affluence, but also through the lanes and alleys — the "Ghettos of the poor." In the eloquent words of "Hyperion," the physician is the servant of the public, "toiling much, enduring much, fulfilling much; and then, with shattered nerves, and sinews all unstrung, lies down in the grave and sleeps the sleep of death, and the world talks of him while he sleeps! And as in the sun's eclipse we can behold the great stars shining in the heavens, so in this life-eclipse does he behold the lights of the great Eternity, burning solemnly and forever."

APPENDIX.

LAWS REGULATING THE PRACTICE OF MEDICINE IN THE UNITED STATES AND CANADA.

Extracts from a Report presented before the American Academy of Medicine at New York, October 10, 1883, by RICHARD J. DUNGLISON, M. D., *and* HENRY O. MARCY, M. D.

THE excellent laws now in force in West Virginia and Illinois have been taken as models, and although it has been found impossible to imitate them exactly, on account of local obstacles and local prejudices, the wedge has been entered, and some good results must inevitably attend the enforcement of the law. A letter recently received from Dr. Millard, the Secretary of the State Board of Minnesota, a State which has adopted restrictive enactments since the last annual report of your committee, summarizes the general aspects of the best of these laws; and we may quote his remarks upon their provisions as particularly appropriate in this connection, especially as he has given the subject of medical legislation close study and attention: —

"I think," says Dr. Millard, "the law or 'Acts' now in force in West Virginia, Illinois, Minnesota, and Missouri the best, by far, extant in any of the States. These four States are governed by virtually the same law, and have a constituency of at least 15,000 physicians. Each Act gives the Board the power of deciding the diplomas of what schools they shall recognize, and of revoking the certificate of any practitioner for unprofessional conduct; also the power to grant licenses to non-graduates by passing the necessary examination to test their fitness. You will observe that the main features of the law of these four States make the Board the Censors of the different medical

[1] See Appendix.

schools, as well as the professional conduct of those practicing within the jurisdiction of the different Boards. It is claimed by the enemies of this Act that it constitutes a 'medical autocracy' of the Board, and that it may use its power very unjustly. There is no doubt that, if the Act is administered by unfair men, this criticism is true. It is, however, noticeable that outside of a few '*commercial*' medical schools the law gives the greatest satisfaction, and I have not heard a whisper of complaint. The profession in general and a few of our leading medical institutions recognize that this country is flooded with incompetent medical men. That the time has arrived to cry, halt! all will assert, but as to the means of bringing about the halt there is a great difference of opinion. That it will not be brought about by the colleges themselves the profession is satisfied after the last ten years' agitation of the subject, and the example set by Bellevue and some others. In appealing to legislatures to regulate this evil I think the correct law should compel *all parties* to submit to an examination before practicing in the State. Such legislation is, however impracticable now, and next to this I think the Acts of the States I have mentioned the best."

The Mississippi State law, which was adopted in 1882, is stated, by an earnest observer in that section of the country,[1] to be on a par with that of Illinois, in its efficiency and practical working, and is said to have accomplished already all that its most sanguine friends could have expected. To quote his own language: "All practitioners in the State, as far as I am aware, of every grade, have cheerfully complied with its requirements. . . . The pile doctors, down to the Indian doctor tramping around with his banjo and his calico gown, have given us a clear field. Their places are vacant, and their voice is heard no more in the land. Thus, already, in one season, thousands of dollars have been saved to the people of the State, to say nothing of other benefits." In Alabama the diplomas of medical colleges confer no right to practice medicine in that State; the applicant must be actually examined by a Board appointed for that purpose. In Arizona and Pennsylvania, and in Washington Territory, the law is simply for purposes of registration; in Arkansas a bill providing that all practitioners should be graduates of reputable medical colleges failed, this year, to pass both houses of the Legislature, and county boards of medical examiners, appointed by county judges, who may not be competent to decide as to the professional qualifications of their appointees, still continue to give certificates to applicants for permission to practice medicine in that State. Connecticut's very brief law is mainly intended for the punishment of itinerants. In Kentucky the law is a dead letter except in a few counties, and in Texas and Nebraska it is weak and ineffective.

Dr. Piffard considers the New York law a good one, but that it has one important defect, in that a perjury in registering is only punishable as a misdemeanor, and not as a felony. Oregon has had a bill before the Legislature every year, for ten years past, but it has not yet succeeded in attaining so desirable a consummation. In Tennessee, which has no law of this kind, the practice of medicine is said to be free to all; according to the authority of the Secretary of the State Board of Health, "Indians, Negroes, confidence men, and all that ilk, ply their 'trade' with no restrictions whatever. Any man who claims to be a doctor *is* one; hence druggists who do not know enough to make a living turn out as doctors in full practice before you know it. A farmer boy, too lazy to plow, reads an old work on practice, or Every Man His Own Doctor, invests six dollars in drugs, and is a physician; and, being a 'regular,' we all consult with him. Our legislators will not touch, and our doctors are too timid to press, the subject, and so we languish in the old paths."

It may well be asked by us, as a committee watchful of the progress of the times, whether, in States like this, which have imposed no restrictions upon the unlimited and unbridled practice of medicine, the experience of nearly four centuries has seen any marked change from the days of King Henry VIII. to the present hour;[2] for we read in the preamble of an Act, passed in England in the year 1511, looking to the regulation of the practice of physic and surgery, that its adoption was rendered necessary by the fact that "the science and cunning of physick and surgery is daily, within this realm, exercised by a great multitude of ignorant persons, of whom the great part have no manner of insight in the same; some also can read no letters in the book, so far forth that common artificers, as smiths, weavers, and women, boldly and accustomably take upon them great cures and things of great difficulty, in which they . . . apply such medicine as be very noxious and nothing meet therefore, to the high displeasure of God, great infamy to the faculty and the grievous hurt, damage, and destruction of many of the king's liege people."

Utah has shown her interest in medical legislation only by that provision of her Penal Code which punishes physicians who are drunk, and has been content with this measure of legislative protection of the people of that section of the country. A correspondent in Salt Lake City writes that "the inference is, that during the little time he is sober he will not do much harm. As for the medical fraternity proper, I do not think any of them care for any law regulating medicine. I believe they are advocates of the doctrine of the 'survival of the fittest.'" Wisconsin might be placed in the list of those having a law to regulate the practice of medicine, but the title indicates that it is simply An Act to prevent Quacks from Deceiving the People by assuming a Professional Title, and not really a law that may be classed in the same category as those mentioned previously.

A FEW MEDICO-LEGAL FEATURES OF LIFE INSURANCE.[1]

BY MAX F. ELLER,

Of the New York Bar, Member of the New York Society of Medical Jurisprudence and State Medicine, Associate Member of the Massachusetts Medico-Legal Society, etc., etc.

THE beneficent institution of life insurance has, in proportion to its extent, perhaps more than anything else, been a fruitful source of litigation. With the exception of criminal law, there is no branch of legal science, both theoretical and practical, which presents so many features of medico-legal interest and which has contributed in such a marked degree to the study, investigation, and judicial settlement of controversies, largely based upon difficult or doubtful problems of forensic medicine. The reasons for this are not far to seek. The physical condition of the applicant for life insurance at and prior to the time of his application, his mode of life, his habits, his family history, the remote and proximate cause of death, nature of death, if known, and still more so if doubtful, suspicious, or mysterious, all furnish abundant and diversified material for misrepresentation, fraud, deceit, and many other sins of omission and commission. A great many persons, otherwise honest and conscientious, consider a life insurance company the legitimate prey of their fraudulent devices and conspiracies. This is not confined merely to persons desiring to insure their lives, but is also extensively practiced by the legal representatives or other claimants for the insurance money after the death of the risk. On the other hand, it must be admitted that, up to within recent times at least, a great many life insurance companies availed themselves of the most flippant excuses and the most frivolous pretexts to defeat honest claims. No doubt this has had something to do with the desire to "get square" at any cost. The law reports are full of cases in which an honest claim was contested on purely technical grounds, or on shallow subterfuges, with an expense of legal and medical learning worthy of a better cause.

It is a sign of a healthier tendency, that at the present time reputable companies content themselves with contesting those cases only which present either an important question, not hitherto judicially determined, or such an array of facts and circumstances of a suspicious or doubtful character, that *not* to make them the subject of judicial investigation and decision

[1] Read at the annual meeting of the Massachusetts Medico-Legal Society, June 10, 1884.

would be placing a premium upon fraud and dishonesty.

You are, no doubt, familiar with the more prominent medico-legal features of life insurance. They are nearly all, if the expression be permitted, of a post-mortem character. From the very nature of the contract between insurer and risk, and from the immense number of risks, scattered over a vast expanse of territory and among all conditions of men, it can easily be inferred that it is practically impossible, except in a few isolated cases, to ascertain before death those facts and circumstances which contribute to make a particular case the subject of medico-legal inquiry and investigation.

The examination of an applicant, both as to his previous history and habits and as to his present physical and mental condition, may be as exhaustive as possible, yet there will always remain a large margin for deception, misrepresentation, and concealment of important features.

Again, it is almost equally difficult to prevent deceit and misrepresentation in the proofs of death if the persons claiming the insurance money are bent upon it. *Almost* equally difficult, yet the chances of discovery and exposure of the actual state of affairs are much better on account of the greater number of persons necessary to the carrying out of the collusive scheme and conspiracy upon which the success of the fraudulent enterprise is based.

One of the most frequent attempts at deception is that of representing a death by suicide to be due to natural causes. This was practiced extensively for a long time and as stubbornly contested by the companies. The moving cause of this class of frauds was the popular fallacy, which up to this day has a great many sincere adherents, that suicide, *eo ipso*, is an evidence of insanity. Believing this to be the case, claimants had no scruples to misrepresent and deceive in order to obtain that to which they considered themselves fairly and honestly entitled, and at the same time avoid the odium of a suicide in the family.

The defense of suicide is now but rarely resorted to, and then only in flagrant cases, although the companies certainly never admitted the theory that suicide was an evidence of insanity. The policies still contain a suicide clause, but it is rarely made the basis of contest, except in cases like the famous Calvocorepes case or the more recent Dwight case, in both of which the attempt was made to establish the fact that unusually heavy insurance had been secured with the preconceived determination to provide liberally for the surviving family by committing suicide after payment of only one or but few premiums, and by giving it the appearance of natural death or homicide.

It seems hardly necessary to state that the defense of suicide cannot prevail if the suicide is actually committed in a condition of mental irresponsibility. Yet, in order to prevent that defense from gaining any foot-hold whatever in such a case, laws have been made declaring that it shall not be a defense if the suicide is committed by an insane person.

Such a law was passed by the Legislature of the State of New York at its last session. The necessity for such a law is apparent when it is considered that the companies have changed very materially the wording, and consequently the legal bearing, of the suicide clause in their policies. That clause formerly read, that the company should not be required to pay and the policy be null and void, if the insured shall die by his own act or hand. It now reads, that the "self-destruction" of the insured is *not a risk assumed by the company*. This makes it incumbent upon the claimants to prove that the risk is one of those which *are* covered by the policy and assumed by the company. As a rule this is a matter of grave difficulty and even impossibility.

The following is a case in point, to show the quandary in which claimants may find themselves under this clause, even when it is admitted that the risk, whether suicide or not, was sane at the time of death: —

Some eight or nine years ago a New York importer was found dead in bed in his boarding house. Nothing was found in the surroundings which would point to suicide, no weapon, poison, empty bottle, etc. The autopsy, performed by the deputy coroner, revealed, however, death by cyanide of potassium, whose odor when the abdominal cavity was opened was so strong that it drove even the coroner from the room. Under the rules of the company the minutes of the coroner's inquest and the verdict of the coroner's jury must be attached to and made a part of the proofs of death.

This had to be done in this case, but the claimants expressly stated that they did not admit the truth of the inquest and verdict, and did not consider themselves bound by them. The company having ascertained that the claimants, under an assignment of the policy, were a firm of creditors of the deceased, who had persistently and continuously dunned and pestered this man, and had thereby doubtless contributed in a large measure to his death, refused payment on the ground of self-destruction. Suit was thereupon brought upon the policy, the defense of the company being that the death of the insured was one of the risks *not* assumed by the company, being one by self-destruction. When the cause came on for trial the company's counsel, in cross-examination of one of the plaintiffs, introduced in evidence the proofs of death with the coroner's minutes and verdict attached thereto, and thereupon moved for a dismissal of the action on the ground that it appeared *primâ facie* that the deceased came to his death by his own hand, and that therefore the risk was one *not* assumed by the company.

The court held that the affirmative must be with the plaintiffs to prove the cause of death, in other words, that the plaintiffs must show affirmatively that the death was the result of one of the causes whereof the risk is assumed by the company. This ruling is in accordance with a decision of the United States Supreme Court in a leading case.

How could the plaintiffs, in the face of the coroner's verdict, prove that the death was a natural and not a self-inflicted one?

Under the law of New York, suicide, in order to be an available defense, must be proven by the party setting up such defense to have been the act of a sane person. The *onus probandi* is thus shifted, and justly so, both from a legal and equitable stand-point. The law does not and ought not to encourage any person or corporation to shield themselves by cunning devices and shrewd expedients against the consequences of their contracts and obligations.

On the other hand, there is no doubt that it is fallacious and illogical, as well as unscientific and unpsychological, to claim every suicide as the act of an

insane person, and to condemn the defense of insanity *in toto* on that ground.

The New York Penal Code makes it a felony to commit an attempt at suicide. While this is undoubtedly mistaken severity and wholly indefensible on corrective and philanthropic grounds, yet the underlying principle is a sound and just one, that is, that attempted suicide is not necessarily the deed of a person of unsound mind, but is an act which, though only directed against one's self, is more or less a violation and infraction of the rights of person, and is therefore punishable.

That it is a breach of contract for an insured sane person to lessen the probable duration of life by his own act cannot be denied. It matters not whether poverty or business reverses, unrequited love, or fear of punishment cause the act. Why should not a corporation have the right to consider a contract rescinded or violated for good and sufficient cause the same as a private individual? The answer is that in many cases, though hardly ever with the large and substantial companies, the keen competition and active rivalry between the companies has made it a matter of expediency and business policy for them to pay every claim, unless the fraud be a very gross and palpable one.

A great many cases have been published both in books and in the daily and periodical press, which are replete with the most interesting facts, especially those of mysterious disappearances, fraudulent suicides, fictitious burials, etc. Yet the most interesting cases from a medico-legal point of view are those where misrepresentations and concealment have been perpetrated by an applicant for insurance, or where the proofs of death have been so manipulated and falsified, either by the family or by friends and other interested parties, that it is very difficult, sometimes almost impossible, to ascertain the truth, which when at last found and established, ought to, if it does not, operate as a complete barrier to the payment of the loss.

There are three principal classes of cases which come under this category: —

First. Those where the applicant makes an intentional misstatement or concealment of the truth as to family history or previous illnesses from certain diseases, which, if admitted, would defeat the application. These cases are very frequent and most difficult to ascertain and prove. In a country like this, with its ever shifting, restless population, it is well nigh impossible to establish the truth or falsity of a person's declaration as to family history in regard to diseases which are commonly accepted as capable of hereditary transmission.

Then, again, how easy is it for a risk to claim entire ignorance of the existence or suspicion of any hereditary taint. In a long and varied experience in the investigation of doubtful and suspicious cases on behalf of one of the most prominent life insurance companies of the United States I have succeeded in but one case to demonstrate to the satisfaction of the company, and for that matter also to that of the claimants, that the representations as to the absence of hereditary taint were willfully false and knowingly untrue. This was a case where a prominent manufacturer in a large city of the Middle States had not only his own life, but also that of his three sons, insured for large amounts. The physical examinations were highly satisfactory, and all four were considered extraordinarily good risks. Within a few years the three sons, all of them at the time of death barely twenty-two or twenty-three years old, had died of phthisis pulmonalis, while the father continued to live in the enjoyment of the most rugged health. The death of the third son, following so shortly after that of the second and first, put the company upon its inquiry. I was requested to investigate the family history, without regard to time, trouble, and expense, and I succeeded, after the most patient and laborious searches, in a large number of places in city and country, in records of births, marriages, and deaths, cemetery and burial books, etc., etc., in obtaining a pedigree of that family for five generations back, which showed most conclusively the hereditary transmission of the disease on the mother's side, it appearing every second generation with surprising regularity. It goes without saying that the father of the three sons, *to whom all this was known*, when confronted with the proof, admitted the fraud and made even partial restitution.

Another interesting case which came under my observation, was that of the intentional concealment of a previous illness, which, if known to the company, would have debarred the applicant from insurance. It is often claimed, by those who find a particular delight in disparaging life insurance and the protection which it is bound to give to its beneficiaries, that the company, once having accepted a risk and having received the premium, ought not to try to "crawl out" of its just obligations by protecting and defending itself against such "trifles" as a few mistakes about previous illness, caused by so-called forgetfulness, absent-mindedness, etc., etc. The following case contains, perhaps, the best answer to these apologists of fraud and deceit: —

A prominent New York merchant of high business and private character obtained an insurance of $5000 on his life. A few years thereafter he applied for a second policy. The examination was entirely satisfactory. The application among other questions contained this one, "Have you ever suffered from gallstone?" To this he answered "No." The second policy was written also for $5000. Six months afterwards he died. The proofs of death stated as the remote cause of death "biliary calculus;" as proximate cause of death "ulceration and rupture of gall-bladder and internal hæmorrhage; duration of last illness twenty-five days." Now, like Rome, biliary calculi are not built in one day, and an investigation became necessary to ascertain, if possible, how long this man had suffered from biliary trouble. Permit me to say here, before completing the history of this case, that a coroner's or medical examiner's inquest, compared to the investigation of a doubtful or suspicious life insurance case, is but child's play. The family of the deceased are, of course, if not openly against you, at least non-committal and non-communicative; friends or acquaintances as a rule know very little or nothing about the essential and material facts. If they do, they have no inclination to tell what they do know for fear of being called upon to testify. The doctors immediately seek refuge and shelter in that convenient and charitable asylum called "privilege." Obstacles and closed mouths everywhere, open or concealed hostility on all sides, dust in the eyes, if possible, anything, every-

thing to prevent the truth from becoming known. The family physician is the most formidable obstacle. Self-interest, professional privilege, perhaps fear of detection of mistaken or unskillful diagnosis or treatment, all these contribute towards making him as silent as a sphinx, except as to the facts absolutely necessary to be stated in the proof of death. In the face of all this active and passive opposition the investigation must be carried on. A proper regard for the interests of other risks requires that a palpably fraudulent claim should be opposed, but it must be satisfactorily proven to be a palpably fraudulent one. This cannot be done, nor can an unfounded suspicion be dispelled, without the most thorough investigation. In the case mentioned, the following facts were ascertained after an exhaustive and searching investigation: In the winter preceding his second insurance, this merchant was attacked by a dangerous illness, caused by an obstinate constipation, which finally settled into an utter inability to defecate. Peritonitis followed. Several prominent physicians were called in consultation, not all together, but successively. Every one of them, independently of the others, diagnosticted the disease as a severe attack of biliary calculus. The peritonitis finally assumed the most alarming character. All remedies had failed to produce a movement of the bowels, and the patient was given up. He had been told by at least two of the physicians what the nature of his illness was, that it was "gall-stones." He begged that a certain physician, whose fame as a specialist in intestinal diseases had reached him, be sent for as a last resort. This was done. Copious injections of warm water, suggested by him, brought on the long delayed movement, and the patient recovered. This last physician also advised him of the nature of his illness, and warned him of its almost certain recurrence. Hardly had the patient recovered when he, no doubt bearing in mind the doctor's prophecy, proceeded to an attempt at defrauding the company out of five thousand dollars by fraudulent concealment of the true state of affairs. Can it be expected that the company in a case like this should submit to imposition and pay the policy?

Another very interesting case was that of a young man, whose life was insured for $10,000. A year afterwards he died. The remote cause of death was stated as general paresis, and the immediate cause as maniacal exhaustion. Investigation showed that prior to his being insured he had been afflicted with a severe attack of tertiary syphilis requiring protracted specific treatment. As soon as the evidences of that disease had disappeared, he took out the policy, carefully concealing the fact of his having suffered from venereal disease. Would he have been accepted as a good risk if he had told the truth and concealed nothing? The history of his last illness, laboriously obtained from reluctant and hostile witnesses, showed that the paresis was caused by or was the consequence of the syphilitic lesion, and that he received up to his death and while in the private lunatic asylum, where he died, specific treatment. Yet some of the physicians attendant upon him endeavored to make it a case of sclerosis of the posterior columns and of tabes dorsalis of other than venereal origin, and denied the specific treatment. Notwithstanding all these denials and evasions, the investigation established conclusively two facts: first, that the risk died of a disease which was the consequence of tertiary syphilitic lesion, and, second, that this lesion existed and was known to the risk to have existed before the policy was applied for. Will it be seriously contended that the company should acquiesce in such a fraud and offer no resistance to the claim based upon it?

It has been stated before that one of the chief obstacles in the way of a thorough and exhaustive probing of cases of this class is the rule, and what physicians understand and claim to be the rule, as to privileged communications. It must be confessed that the decisions of the courts, especially in the State of New York, are decidedly unfavorable to the publication by testimony or otherwise by a physician or surgeon of *any* information acquired while attending the patient, and that only the patient himself can absolve the professional attendant from the obligation of secrecy.

Section 834 of the New York Code of Civil Procedure says: "*A person duly authorized to practice physic or surgery, shall not be allowed to disclose any information which he acquired in attending a patient in a professional capacity, and which was necessary to enable him to act in that capacity.*" Our courts have held that this applies not only to facts and circumstances communicated by patient to doctor, but also to knowledge of facts and circumstances of his physical condition ascertained and acquired by the physician from attendance upon the patient, without being directly informed thereof by the patient.

Of course professional confidence ought to be protected to the fullest extent, as otherwise unscrupulous or recklesss professional men might be enabled to do a vast amount of mischief, either from mere carelessness and want of discretion, or for purposes of gain. But it is a serious question whether, as between parties to a dispute or controversy, justice should fail, so that the professional privilege may remain inviolate even when it is relied upon to protect from the consequences of fraud and deceit.

I venture to say, and I know that in saying so I place myself in antagonism to many able judges and lawyers, that the rights of society and the demands of justice and equity ought to be superior to the rights of individuals; that the law ought not to allow any man whose knowledge (not information) is necessary and material for the establishment of exact justice to withhold that knowledge from the court, and thereby perhaps defeat the overthrow of a vicious and fraudulent claim.

Take the above case of biliary calculus, for instance. There some of the attending physicians informed the patient of the nature of his illness. Their knowledge of its character was and must have been to a considerable extent obtained from information furnished by the patient himself. Should the testimony of those physicians be ruled out and a flagrant fraud be countenanced? For upon that fact hinges the entire issue. If the patient knew that he had biliary calculus and concealed that fact, that ought to be an end to the claim.

It has been my good fortune, in the many cases which I have investigated, to convince a large number of physicians that in giving the history of a case from notes of their observations only, they violate neither the spirit of the law nor that mysterious professional, shall I call it entity or nonentity, to wit, ethics. Those who could or would not be convinced had to be made to talk by stratagem, — the end justifies the means.

There is nothing the average physician delights in more than to find some poor victim at whom to fire broadsides of technical terms and scientific definitions. The saying is, that a little learning is a dangerous thing, but when a layman reads up a few generalities and elementary points on some particular medical question which he likes to have elucidated, the little learning generally is a dangerous thing — not for the layman. I have found this to work exceedingly well in many cases. The little learning shows the layman to be a man of some education, all the more easily, so the doctor thinks, to be impressed with Greek and Latin words, etc., because some of them are at least partially understood. Of course the main point is willfully misunderstood and misapplied by the layman, thus rendering a fuller explanation and further details necessary to deepen the impression. Then the layman begins to understand, but not yet fully. More explanations, more details, more questions and answers, and very soon the layman knows all he cares to know. The doctor imagines that he has impressed the interlocutor with his profound learning, but the latter has himself learned a thing or two. This process is not patented, and is cheerfully and unselfishly dedicated to the medical examiners of Massachusetts for use in their intercourse with the legal profession.

Second. The second class of cases are those where the applicant makes an intentional misrepresentation or concealment of the truth as to mode of life or habits, which, if admitted, would defeat the application. The majority of cases arising under this category are those of intemperance, although there are also occasionally cases of extra-hazardous occupations, which would, if stated, render the acceptance of the risk extremely doubtful. The habitual excessive use of alcoholic beverages has in its train a variety of dangerous diseases, such as probability of early death, exposure to fatal accidents and violent abbreviation of life, and for these reasons excludes applicants addicted to such habits. Their concealment, therefore, becomes necessary if insurance is sought, and it is astonishing what an overwhelming proportion of teetotalers and temperance men there is in this world, if the compilation of statistics be based exclusively upon life insurance tables. The moderate use of stimulants is not forbidden or deprecated, yet the majority of applicants, for fear of being rejected, refuse to admit even that. There seems to be no reason why the concealment of this habit, or whatever you may call it, should not vitiate the policy. The point to consider is, Would the risk have been accepted if he had been known to be a drinking man? And as the answer is an emphatic No, the answer to the question as to the liability should be the same.

A case in point is the following: A New York merchant of very convivial habits conceived the idea of providing for his family by securing a $10,000 policy, and then drinking himself to death. He had been a hard drinking man for years, which, of course, the company did not know. In furtherance of his design he did what he otherwise would not have done, he kept sober for a number of months, and, being a man of originally sturdy constitution and powerful frame, succeeded in destroying, or at least obliterating for the time being, all traces of his intemperate habits. His examination was eminently satisfactory. Among other things he stated that he never drank alcoholic liquors. The policy was issued, and within eight months thereafter he died of delirium tremens.

It was subsequently shown that from the day of the issuance of the policy to the day of his death his life was one continuous "spree," without any sober intervals.

The company refused to pay, the case was taken into court by the beneficiary, the widow, and the result was, as anticipated, a compromise.

This ending deserves nothing but censure, being but the compounding and condonation of a palpable fraud from motives of expediency and business interests. If the company had insisted upon a trial it would doubtless have received a verdict in its favor.

Third. This is a class of cases in which a forbidden occupation or journey is entered into, or a habit, detrimental to health and life, is acquired after the policy has been issued, and where the cause of death is attributable to such occupation, journey, or habit.

As to the first two (occupation and journey) the point is very clear. The latter (habit) presents a very interesting medico-legal question.

Habits of intemperance often degenerate into a condition which, in the light of modern medical research, cannot be regarded as anything else than a disease. Dipsomania, inebriety, alcoholism, whatever you may call it, is recognized and treated as a disease, and has found a distinctive place in the system of medical science. No one pretends to hold a person responsible for being afflicted with a disease, except it be self-inflicted or brought about by deliberate and willful exposure. Should a person with predetermination expose himself to the contagion of a dangerous disease, it would perhaps be very difficult to prove that such was the case, but should he deliberately use alcoholic stimulants or narcotics in excessive quantities and thereby acquire a habit which finally and imperceptibly changes into a disease, which is beyond his control, the matter would be quite different. In the latter case the perhaps at first involuntary foundation is laid for an impairment of those mental faculties and factors which, if in a normal condition, would be formidable obstacles to the physical change. In short, a physical habit is allowed to become a mental and physical disease, which is beyond the control of the individual just as much as typhoid fever or pleurisy.

Should such a tendency and proclivity be allowed to defeat a policy? To one who endeavors to be thoroughly impartial in matters of life insurance the answer must be unreservedly and emphatically a negative one, both from a medical and from a legal ground.

Fraud vitiates every contract, and for that reason the misrepresentations and concealments of applicants or others have been justly condemned, but in the class of cases under consideration there is no fraudulent intent; the minds of insurer and applicant meet on an honest, truthful basis. A guarantee by either party to do that which may be and undoubtedly is *ultra vires*, or to state it more correctly, not to do that which may and generally is *in futuro*, cannot and ought not to be enforced. The frailties and weaknesses of human nature must be considered, and the law, as applicable to the relations of individuals among themselves and to others, does take cognizance of them. If it did not it would not deserve its name. *Ultra vires nemo cogi potest* is as old as it is true. This class of risks the companies ought to assume, all conditions and provisions of their policies to the contrary notwithstand-

ing. Supposing the drinking habit is acquired by a patient to whom stimulants have been prescribed by a physician, and who continues their use after the necessity therefor has ceased to exist, simply because he contracted the appetite. Such a case came under my observation not long ago. It is very difficult, in the majority of instances, to ascertain the exact time when the habit was contracted and when it ceased to be a habit and became a disease. The defense of bad habits acquired subsequent to the issuance of the policy ought, in order to be consistent, to include all cases where the illness and death were the consequence of any and every kind of indulgence, nay, even of a reckless exposure to cold or heat or the seductive wiles of cucumber salad. Where would this lead to? There would be a defense to nearly every loss.

In the relation of insurer and insured there must necessarily be some *risk* beyond that of the probable termination of life based upon mortality statistics. It forms the basis of the relation, it is its vital point, and should have as liberal an application as is consistent with justice and equity.

There are numerous other medico-legal features of life insurance which furnish interesting data of investigation and discussion, but those mentioned in the foregoing pages are perhaps of the greatest importance.

The companies, as a rule, have not only from necessity, but as a result of enlightened administration and adaptation to the progress of science, kept pace with the advancing spirit of the age and the demands of modern research. Their medical work, both as regards statistics of mortality, epidemics, physical and chemical examinations and problems of mental responsibility, etc., has been done conscientiously and scientifically, and has been and is fruitful of valuable contributions to medical science in its theoretical and practical aspects. Their legal work has to a great extent thrown off the shackles of narrow-minded technicality and slavish interpretation, and, while not yielding one iota to the demands of the blackmailers and rogues, has sought to infuse the dealings of the corporations with claimants and beneficiaries with a commendable spirit of fairness and liberality which is the very essence of justice among men. To both combined we owe much valuable material for scientific research and beneficial discussion of mooted points.

If the preceding remarks have in any way contributed towards stimulating further progress and study of medico-legal science as applicable to life insurance, they will find in that result a welcome justification.

— The following model certificate is said by the *Chicago Weekly Medical Review* to have been copied by Dr. P. S. Conner from the records of the Pension Office in Washington: "The braud muscle which compresses, lowers, and extends the linea alba, the muscle of expiration is entirely severed thereby affecting the scorbutus cordi, which goes straight up to the navel or umbilicus, and from thence down to the pubis which is evidently the primordial cause of the frequent abscesses of the scrotum. Also from the fact of increased attachment necessarily causes increased cicatrix which is constantly increasing, and hence the increase of all the detrimental symptoms."

A CASE OF DIABETES INSIPIDUS.[1]

BY SAM'L. AUG. FISK, A. M., M. D. (HARV.),
Professor of Descriptive Anatomy, Medical Department of the University of Denver, Denver, Colorado.

IT is always a delicate matter for a man to herald his bodily infirmities, and the reader, in this present instance, feels a hesitancy in presenting his own for the consideration of his professional brethren; but he has thought that the rarity of the disease to be spoken of and the fact that it has occurred in one who, by virtue of his being a physician, can note the symptoms with accuracy, would justify him in making this report, and that these considerations would also be a sufficient excuse for his being personal.

History. The subject of this disease is twenty-eight years old, and has, until within a few years, enjoyed health, although he has never been robust. When he was five years old he had an attack of "congestion of the lung." At fourteen years of age he was taken with acute inflammatory rheumatism, which lasted ten days or two weeks, and involved the joints of the ankles, knees, shoulders, and wrists, but did not affect the heart. Six years ago, in the spring of 1878, he was sent away from Boston, by the late Dr. Calvin Ellis, because it was found that there were dullness and subcrepitant râles at the base of his right lung, which signs cleared away without confining him to his bed. Two years later, in the spring of 1880, he was sick in bed for four weeks with a lobular pneumonia, — the acute catarrhal pneumonia of Niemeyer, — involving that portion of the lower lobe, on the left side, under and around the nipple. As this inflammation did not go on to resolution, but rather showed a tendency to spread, he was sent into the White Mountains for the summer, and in October of that year he came to Colorado. In November, 1882, he was examined by Dr. Austin Flint, Sr., and was told that one side of his chest was as sound as the other, and that no trace of the old trouble remained. So much for the personal history up to the time of the present attack.

The family history shows that his grandparents died in old age, except his maternal grandfather, the cause of whose death he does not know. His parents died in middle life, each of a valvular lesion of the heart. Brothers and sister are living and well. Three uncles on the father's side are known to have diabetes mellitus.

In October, 1883, while the reporter was busily occupied with professional and literary work, he noticed that he was passing a large amount of urine, but he did not make any measurements of the quantity. It must, however, have been at least double the normal amount. On the 31st of October he was attacked with inflammatory rheumatism, which proved to be subacute in its nature, and lasted, with the relapse, for six weeks, during the greater part of which time he was confined to his bed. The joints affected were the knees. The treatment was the salicylate of soda, in five-grain doses every three hours, in the early stage of the affection. Later, the acetate of potassium, twenty grains three times a day, was added, and for the last two weeks he was put on to salicin, ten grains every three hours, and the knees were painted with cantharidal collodion. All through the attack hypo-

[1] Read before the Denver Medical Association, Tuesday evening, May 13, 1884.

dermic injections of morphine, from a quarter to a third of a grain, were administered at night, and he was given ice to chew *ad libitum*.

Synchronously with the onset of the rheumatism the reader suffered from excessive thirst and a craving for the alkaline waters, such as Vichy. The artesian water tasted as though it were sweetened with molasses, and milk left a thick spittle in the mouth, while Vichy, or the iron Ute water, was palatable and "clean." These latter waters were obtained on draught at the fountains, and the average amount drunk *per diem* for nearly six weeks was two quarts. The total ingestion of fluids was about ten quarts a day, and the daily secretion of urine was from nine to ten quarts. An analysis of the urine showed: color, pale; reaction, slightly acid; specific gravity, 1003; albumen and sugar, absent.

The reader wishes to place especial emphasis upon this matter of excessive thirst. It was extraordinary, as the tongue and fauces would be parched and dry, even after drinking. The skin became furfuraceous, and the fingers puckered and so horny that the epidermis could be cut off as though from a corn. The delicacy of the sense of touch was impaired, and for weeks there was no moisture apparent anywhere on the body; in fact, it was impossible to produce sweating. Every once in a while a prickling, itching sensation would be felt in the skin, especially in the small of the back and on the inner side of the thighs. The emaciation produced by the rheumatism was marked, and there was, of course, great loss of strength. Convalescence was slow, and during it the polydypsia and hyduria continued. Water was the more palatable for being ice-cold, and the urine had to be voided nearly every hour. Thirty drops of dialyzed iron and three grains of the sulphate of quinine were taken three times a day.

About January 1, 1884, that is, after three weeks' trial, the quinine was discontinued, and the tincture of the chloride of iron was substituted for dialyzed iron.

As the reader supposed that the polyuria would disappear with the return of strength he did not pursue any treatment with especial reference to it beyond having a careful regard to follow a healthful regimen. With the return to his accustomed weight the tips of his fingers became rounded, and although the skin had previously been so dry that it cracked around the nails it now became somewhat moist, and perspiration occasionally appeared in the palms. It might be well to state, in this connection, that, in October, previous to the rheumatic attack, the prick of a pin over the inner edge of the gastrocnemius muscle of the right leg had produced sores which eventuated in regular eczematous ulcers. During the early part of January, 1884, the daily secretion of urine continued to be large, and an analysis showed the results to be the same as recorded, except that the specific gravity was lowered to near 1000. The bladder had to be emptied every hour, or hour and a half at the utmost, and the usual amount at each voiding was from 400 to 600 cubic centimetres. Of course this constant micturition interfered with sleep, as it necessitated the getting out of bed from six to ten times every night to pass water. The average secretion at night, during the sleeping hours, was and is at least 3000 cubic centimetres, and it reaches as high as 4000 cubic centimetres.

January 20, 1884. Ten drops of Squibb's fluid extract of ergot was given three times a day, and the treatment continued for two weeks; then the dose was increased to half a drachm, and finally to one drachm, three times a day, until four ounces in all had been taken. There was no decrease in the amount of urine, but the effect on the general health was so bad that the ergot was discontinued. The appetite was affected, and the sight of food nauseating. Constipation and flatulence existed, and the pulse-rate fell from 96 beats to 82 or even 76 a minute. The ergot produced marked muscular weakness, so that walking became an effort and was exhausting, and the patient noticed a tendency to go to the left in walking. When the drug was abandoned these symptoms disappeared, the appetite improved, the strength returned, and the functions of the bowels became normal.

After the patient had been under the treatment by ergot for two weeks a quantitative analysis of the urine was made. The solutions used and the methods employed were those recommended by Tyson. The utmost care was taken in the preparation of the solutions and in performing this and all subsequent analyses, and it was hoped that the results would be accurate. They were as follows: —

February 6, 1884. Daily amount of urine, 9000 cubic centimetres; reaction, very slightly acid; specific gravity, 1000; color, in small quantities, very pale; in larger amounts, a light greenish-yellow; odor, when freshly voided, slightly sweetish, like new-mown hay, but not marked; urophæine, the palest amethyst; indican, almost *nil;* earthy phos., scarcely a trace; alk. phos., very slight; albumen and sugar, absent; urea = 30 grammes; P_2O_5 = 2.1 grammes; SO_3 = 4.4 grammes; sediment, absent.

February 13, 1884. After taking drachm doses of ergot it was found that the amount of urine was 10,000 cubic centimetres; specific gravity, 1000; reaction, neutral; color, odor, and sediment as recorded above; urea = 40 grammes; P_2O_5 = 2.4 grammes; SO_3 = 4.4 grammes.

February 20, 1884. A week after the discontinuance of the ergot the results about as above.

March 1, 1884. Began the administration of

℞ Ferri et quiniæ citratis . . . . . gr. v.
Ex. nucis vomicæ . . . . . gr. ¼. M.

to be taken three times a day; also a half a drachm of Squibb's fluid extract of uva ursi three times a day. At the same time an eighth of a grain of the sulphate of morphia was given by the mouth three times a day, and seven drops of Magendie's solution were administered hypodermically at night. This latter amount acted as a stimulant, producing a mild delirium, which kept the patient awake for several hours after its administration, and also made him feel listless on the following morning.

The morphine was taken in this way for a week, and was then stopped for a few days, to be continued for another week.

March 27, 1884. After the above treatment strength and appetite good. Skin nearly normal. Weight one hundred and forty-seven pounds, full weight. Thirst and frequent micturition as annoying as ever. Analysis of urine: amount, 10,000 cubic centimetres; specific gravity, 1000; reaction, color, and odor as before; urea = 53 grammes; P_2O_5 = 2.2 grammes. This large amount of urea may have been the result of a nitrogenous diet, or have been caused by the work that the reader was doing at the time, as he had been

engaged pretty steadily during the month in writing for publication.

After an interval of ten days or so, during which all medication was discontinued, the exhibition of

℞ Zinci valerianatis . . . . . gr. v.
Ferri et quin. cit. . . . . gr. iij.
Ex. nucis vomicæ . . . . . gr. 1-7 M.
Sig. To be taken three times a day.

was taken up and continued for two weeks, and at the end of that time an analysis of the urine was made with the following results: —

April 23, 1884. Weight of patient, one hundred and forty-seven and a half pounds. Amount of urine for twenty-four hours, 9000 cubic centimetres; specific gravity, 1002; color, odor, and reaction as recorded before; albumen and sugar, absent; urea = 38.96 grammes; P_2O_5 = 2.4 grammes; SO_3 = 24.7 grammes. Appetite and general condition good. Skin moist, though still somewhat horny over the knuckles. General strength good, as was shown by the ability to walk long distances without fatigue. The total ingestion of fluids was at least 10,000 cubic centimetres. The thirst and frequent micturition continued as they had been all along. At this time the exhibition of all drugs was discontinued.

Remarks. The prominent features in the case just narrated are the secretion of a large amount of urine, of a low specific gravity, and the excessive thirst. For six months and over the average secretion of urine has been about 10,000 cubic centimetres *per diem*, while the daily ingestion of fluids has been fully as large.

The question might be raised in this connection as to whether the polyuria was produced by the polydypsia, the latter being the result of habit. The reader is convinced that such is not the case. In the first place there is evidently an inherited predisposition to diabetic troubles, then the onset of the disease was sudden, and from the first the thirst was excessive. The reader has tried to control this craving for fluids by eating ice, by drinking lime-juice, and also by drinking dilute H_2SO_4, by sucking lemons, and by limiting the amount of fluids ingested, and all of these measures have been of no avail. After abstaining from drink for a longer time than usual the thirst will become so intense that it requires a larger draught than usual to be satisfying and to give relief. Indeed, it seems to be absolutely necessary that the ingestion of liquids during the twenty-four hours should be somewhat in excess of the amount of urine voided in the same time.

The amount of urine secreted in an hour has been measured frequently, and it has been found to average about 500 cubic centimetres. For comfort it is necessary to empty the bladder every hour during the day, and if the time runs to an hour and a half the discomfort is extreme.

The secretion during the sleeping hours is between 3000 to 4000 cubic centimetres, and it requires that the patient should get out of bed about six times during the night for the sake of emptying his bladder.

In regard to the relation of the polydypsia to the polyuria Dr. Flint remarks, "There is no advantage in limiting the amount of fluids ingested. On the contrary the patient is rendered thereby uncomfortable, irritable, and the consequence is otherwise hurtful."

Dr. Brunton, in Reynolds', writes: "Acting on the notion that the polyuria was a consequence of polydypsia patients have been put on a limited amount of fluid, but without any good result, the tormenting thirst becoming increased, and the general condition worse."

Senator, in Ziemssen, says: "A *sudden deprivation* of ingested fluids may, on the other hand, not only have an injurious effect upon the subjective condition of the patients, who are much distressed by the thirst which torments them, but may also seriously endanger life by the drying of the tissues which is thus produced." In another place he writes: "It is to be noticed, however, that at any rate in a large majority of cases the thirst and the greater ingestion of fluids are secondary phenomena, dependent upon the increased diuresis." The reporter can testify that in his own case an interval of an hour and a half without the ingestion of any fluid produces a thirst as intense as he formerly was wont to experience after walking several miles on a hot day.

He has also noticed that intense mental application, as that of a game of chess or any nervous excitement, increases the activity of the secretion of the urine. The inconvenience of having to micturate frequently is most annoying, and has placed its subject in many embarrassing situations. Fortunately, although the night's rest is interrupted so frequently, it is sufficient in amount, and is refreshing.

The largest part of the fluid ingested is, of course, water, and almost invariably artesian water.

ANALYSIS OF ARTESIAN-WELL WATER.

Temperature	50½° F.
Color	Clear.
Smell	None.
Taste	Pure.
Reaction	Neutral.
Hardness	1.5
Suspended substances	None.
Free carbonic acid	1.05 grs. per gallon.
Solids (sol. in H_2O) consisting of carbonate of potassa	1.01 grs. per gallon.
Carbonate of soda	10.28 grs. per gallon.
Trace of chlorine and sulphuric acid, less than one tenth gr. per gallon.	

The *water does not contain* lime, magnesia, iron, or other metals; *does not contain* ammonia, sulphuretted hydrogen, nitrous acid, nitric acid, or organic matter.

Drugs. Dr. DaCosta has reported a case that was cured by the administration of the *fluid extract of ergot* in large doses. On the other hand, Dr. Tyson failed to get any good results by giving ergot in drachm doses. The theory of the drug's action in these cases is that it contracts the dilated renal capillaries, and hence diminishes the amount of blood supplied to the kidneys. In the present case ergot in drachm doses had no effect upon the secretion of urine, but it produced the most unpleasant effects upon the general health. *Morphine* was given on the theory that it would have a sedative effect on the nervous system, and also relieve any irritability about the sphincter of the bladder. It was taken in doses sufficient to produce a dryness of the fauces and a tingling sensation of the skin together with an itching of the nose. It produced, perhaps, a slight diminution in the amount of urine secreted, but the effect was not sufficient to warrant the continued exhibition of the drug. Morphine was given hypodermically at night in order to thoroughly narcotize the patient, and thus break up the habit, if habit it was, of his having to get up so frequently to void his urine. But when it was found, by a trial of several nights, that seven drops of Magendie's solution would produce a delirium which would keep the patient awake for several hours the experiment was not continued.

As the reader's attention was called to reports of cures from the use of the *valerianate of zinc* in five-

grain doses he determined to give that treatment a trial, but here, too, the results did not justify a continuance of the remedy. So far the effects of the drugs employed have not been good. There was, perhaps, a slight diminution of the thirst and of the secretion of urine under the morphine treatment, but they were not sufficient to justify the subject in taking the risk of contracting the opium habit.

Analyses of Urine. These were made with care, and the solutions were prepared according to the directions given in Tyson's work. I had expected to be able to give results which would be absolute and accurate, and until quite recently I had supposed them to be so. Within a few weeks, however, I have made further analyses which have made me somewhat distrustful of my solutions. These are two young men of nearly the same age and weight as the reader, and who are living under precisely the same condition as regards food, sleep, etc., as he.

CASE I. Age, thirty years. Weight, one hundred and forty-four and a half pounds. Analysis of urine, made April 20, 1884, shows: Amount, 1000 cubic centimetres; color, amber; reaction, slightly acid; specific gravity, 1024; albumen and sugar, absent; urea = 37.962 grammes; P_2O_5 = 2 grammes; SO_3 = 19 grammes. Sediment, a slight cloud, containing mucus and some dust.

CASE II. Age, twenty-six years. Weight, one hundred and forty-nine pounds. Amount of urine, 900 cubic centimetres; specific gravity, 1022; color, slightly high; reaction, acid; albumen and sugar, absent; urea = 31 grammes; P_2O_5 = 2.15 grammes; SO_3 = 13.95 grammes. Sediment, slight cloud, containing a considerable number of calcic oxalate crystals, which may have come from fermentative changes or a gouty diathesis, which he inherits, and some mucus and pavement epithelium.

Two other analyses were made in the cases of other young men in health and of nearly the age of the reader.

CASE III. Age, thirty years. Weight, one hundred and seventy-two pounds. Amount of urine for twenty-four hours, 900 cubic centimetres; color, amber; reaction, acid; specific gravity, 1023; albumen and sugar, absent; urea = 28.5 grammes; P_2O_5 = 1.83 grammes; SO_3 = 21.6 grammes. Sediment, slight, consisting of mucus and a few middle-sized, round epithelial cells, probably urethral.

CASE IV. (May 3, 1884.) Age, twenty-six years. Weight, one hundred and forty-seven pounds. Amount of urine, 1100 cubic centimetres; color, amber (slightly high); specific gravity, 1030; reaction, acid; albumen and sugar, absent; urea = 38.5 grammes; P_2O_5 = 3.146 grammes; SO_3 not taken. Sediment, slight cloud, containing mucus, a few crystals of calcic oxalate, and some spermatozoa.

For the sake of comparison we will tabulate these results, and place them in contrast with each other and with the normal standards given by Tyson, in the accompanying Table.

A consideration of this table shows us that the diabetic patient was secreting about nine times the amount of urine that the other men did, and that consequently while the total amount of solids contained in the urine was nearly the same as in the other specimens its specific gravity was very much reduced from the normal, that, in fact, it was only that of spring water. It is evident from the chemical analysis of the urine and from the fact that he is at his maximum weight, that the diabetic is not wasting in flesh. Our table shows us also that in all probability the analyses for SO_3 were erroneous. Indeed, as there is always a question in regard to the purity of chemicals, and as we do not know that any accurate data have been given of the effects of this climate and altitude on the renal secretions, we shall have to consider these results as comparative rather than absolute. In concluding our remarks on the analyses it may be well to state that the tests employed for the detection of sugar were those of Fehling, Trommer, Moore, and Boetger.

	Date.	Weight.	Age.	Amount.	Sp. Gr.	Color.	Urea.	P_2O_5.	SO_3.	Total Solids.

Bristowe writes: "In some cases the patient appears to be well in all other respects, and, except for the continued presence of his infirmity, enjoys life, probably attaining old age. In some cases he presents all the usual indications of diabetes mellitus, and, after a longer or shorter time, dies as ordinary diabetics die."

Bartholow gives the following prognosis, namely: "Although death is rarely due to the disease, the prognosis is not favorable as to cure. In most cases the disease is rather an inconvenience, owing to the fre-

quent calls to micturate and the incessant thirst, than a dangerous malady."

In the latest edition (1881) of Flint's Practice of Medicine we read: "It is not incompatible with good appetite, digestion, and nutrition. It has been tolerated fifty years. The prognosis is favorable as regards the duration of life and the preservation of the general health if the disease be uncomplicated, but it is unfavorable as regards recovery from the disease."

Dr. Brunton, in Reynold's, says: "This disease resists treatment, and is rarely cured. The duration of life, in general, does not seem to be greatly shortened by it." And Senator (Ziemssen) writes: "Permanent recovery from this disease is rare, but death, in uncomplicated cases, is still more rare."

In conclusion the reporter wishes to put on record the fact that, six months after the onset of the disease, he is in the possession of strength, good appetite, and full weight, and the confident hope of being able to bear his full share of the burden of caring for the sick for many years to come.

REPORT ON LARYNGOLOGY AND RHINOLOGY.[1]

BY FRANKLIN H. HOOPER, M. D.

FRACTURE OF THE LARYNX BY DIRECT VIOLENCE.[2]

An accident of infrequent occurrence, and of great interest from a medico-legal point of view. The thyroid cartilage in its normal state is of such a structure that interference with its continuity can only result under very untoward circumstances. The laryngeal cartilages, however, are liable in advanced life to become the seat of ossific deposit, and then to be more easily fractured. The injury in this case resulted from the free use of a piece of wooden rail. The post-mortem appearances were those of death by suffocation. The thyroid cartilage, more especially the right half of it, was broken up into many pieces, one of which hung free in the lumen of the tube, evidencing great violence. Ossific change was very extensive.

TREATMENT OF FRACTURE OF THE LARYNX.

Dr. K. Wagner, of Konigshütte, points out[3] that fracture of the larynx is very rarely met with, and that not even the most experienced surgeons are in a position to derive from personal experience fixed rules for treating this injury. Most observers, however, agree that in such cases the first indication is the performing of tracheotomy to prevent suffocation. Occasionally, where there is much displacement of the fragments, it is advisable to perform thyrotomy. A case is reported of multiple fracture of the larynx which led the author to consider the subject of the treatment of this injury, and convinced him that further therapeutic measures were necessary beyond opening the trachea. The subject of this case was a robust and very powerful man whose neck had been forcibly squeezed in a fight. He remained unconscious for about half an hour, and on recovering himself found that his breathing was very bad. On the following day, when the patient first came to the notice of Dr. Wagner, there was extreme dyspnœa; and, with coughing, much blood, partly fluid, partly coagulated, was brought up. The face, neck, and surface of the thorax were distended through emphysema. There was found to be free abnormal mobility of the left wing of the thyroid cartilage; and during the prompt performance of superior tracheotomy the cricoid was found to be also fractured and partly torn away from the upper ring of the trachea. The patient did well up to the third day after the date of operation, when signs were presented of hypostatic pneumonia on the left side, and there was complaint of acute pain beneath the sternum. On the evening of the fourth day there was free bleeding from the wound in the trachea, and on the following day the patient died. On post-mortem examination there was found to have been mediastinal emphysema and suppurative mediastinitis. The lungs, with the exception of the lower lobe on the right side, appeared quite healthy.

Dr. Wagner thinks now that in any similar case of laryngeal injury thyrotomy would be indicated, not so much for the purpose of replacing any fragments of cartilage, as for rendering the seat of fracture antiseptic, and for maintaining for a time this antiseptic condition. In a recent case of this kind, he would, after having plugged the trachea, incise the larynx in the middle line, and then separate the two wings of the thyroid cartilage so as to be able to see the whole interior of the larynx, and to apply some antiseptic fluid. He would then plug the interior of the larynx with small pieces of iodoform gauze. The wound would thus be rendered antiseptic, the fragments of broken cartilage be kept at rest, and the risk of hæmorrhage be diminished. If there be no longer any danger of infection, a late thyrotomy, it is held, is still justifiable if performed with a view of putting displaced fragments in a better position, and, if the thyroid cartilage be fractured, of uniting the alæ by silver suture. If the fragments of the thyroid cartilage cannot be thus united, or if stenosis cannot be prevented, Dr. Wagner would advocate extirpation of the partially detached portion of thyroid cartilage and even removal of half the larynx. In a case reported by Billroth in which this partial operation had been performed, a good voice was retained, and, at all events, the patient is thus placed in a better position than that of having to go through life with a completely useless and much obstructed larynx.[4]

IRRITATION OF THE SEXUAL APPARATUS AS AN ÆTIOLOGICAL FACTOR IN THE PRODUCTION OF NASAL DISEASE.

The evil effects of undue excitation or disease of the generative apparatus upon the organs of sight and hearing are well known to specialists in these departments. In the April number of the *American Journal of the Medical Sciences* Dr. John N. Mackenzie quotes authorities to prove the fact that immoderate indulgence in venery may lead to derangements of sight was familiar to Aristotle, and that the fathers of medicine recognized some mysterious connection between the ear and the reproductive functions, and that the intimate relationship between the genital organs and those of the throat and neck attracted the special attention of the ancients. While historical facts point to the early recognition of the relationship between over-in-

[1] Concluded from page 80.

[3] Centralbl. f. Chir., No. 23, 1883.
[4] London Medical Record.

dulgence of the sexual powers and morbid conditions of the eye, ear, and throat, the special part which it plays in the production of nasal disease seems to have been heretofore overlooked. Dr. Mackenzie points out the intimate physiological relationship between certain portions of the reproductive system and the erectile nasal tissue. Clinical observation has shown him that: (1.) In a fair proportion of women suffering from nasal affections the disease is greatly aggravated during the menstrual epoch, or when under the influence of sexual excitement. (2.) Excessive indulgence in venery seems to have a tendency to excite inflammation of the nasal mucous membrane or to aggravate existing disease of that structure. (3.) The same is true in regard to the confirmed habit of masturbation. (4.) The coexistence of uterine or ovarian disease exerts sometimes an important influence on the clinical history of nasal inflammation. These observations, therefore, encourage the belief, if they do not establish the fact, that the natural stimulation of the reproductive apparatus, as in coitus, menstruation, etc., when carried beyond its normal physiological bounds, or pathological states of the sexual apparatus, as in certain diseased conditions, or as the result of their overstimulation from venereal excess, masturbation, etc., are often the predisposing, and occasionally the exciting, causes of nasal congestion and inflammation. Whether this occurs through reflex action, pure and simple, or as the sequel of an excitation in which several or all of the erectile structures of the body participate, the starting-point of the nasal disease is, in all probability, the repeated stimulation and congestion of the turbinated erectile tissue of the nose. It is highly probable that this erectile area, so sensitive to reflex-producing impressions, is the correlative of similar vascular areas in the reproductive tract, and that the phenomena observed may accordingly be explained by the doctrine of reflex or correlated action.[1]

DEPENDENCE OF ASTHMA ON DISEASES OF THE NOSE.

Macini describes[2] three cases in which he believes that asthma depended on a pathological condition of the nasal mucous membrane. His first case was a woman aged forty, who, with the exception of bronchitis and slight emphysema, was in good health. For the last two years her nose had been partly stopped up, and she was obliged to breathe constantly through her mouth. She frequently suffered from true asthmatic attacks, chiefly by night. On examination it was found that the nasal mucous membrane was greatly swollen, and that completely blocking the nostrils with cotton wool increased the severity of these attacks. The nostrils were made pervious by the galvano-cautery, with the result of curing the attacks, and enabling her to sleep peacefully. The second case was that of a woman aged thirty-four, whose right nostril was blocked by mucous polypi; her difficulty of breathing was cured by removing the polypi. The third case occurred in a man, aged forty, who had suffered from his youth from frequent attacks of coryza and difficulty of breathing. He gradually grew bronchitic and emphysematous, and his nose became blocked by considerable swelling of the mucous membrane. The difficulty in breathing increased gradually, till he suffered from attacks of true asthma. As soon as the obstruction in the nose was removed his asthmatic attacks became very much less severe. Macini considers that in these cases the asthmatic attacks were reflex, caused in susceptible persons by a peripheral stimulation of the nerves in the mucous membrane of the nose.

LYMPHATIC DISCHARGE FROM THE NOSE IN LEUCOCYTHÆMIA.

Dr. Cornil[3] relates the case of a patient suffering from leucocythæmia who had a discharge from the nose of a thick, transparent, glairy fluid. It flowed slowly but constantly, and was neither thin like the discharge of a commencing coryza nor opaque like that of a more advanced nasal catarrh, but contained a large quantity of white corpuscles. The patient did not sneeze, nor were there any tickling sensations in the nose. At the autopsy the mucous membrane of the nasal fossæ was seen to be smooth, without ulceration, but thickened in places. The thickened parts presented a gray color on section. They were formed by an infiltration of the connective tissue with a mucous, transparent fluid like lymph. It was this leucæmic infiltration of the Schneiderian mucous membrane which was the cause of the nasal lymphorrhœa.

THE VALUE OF CERTAIN SINGLE SYMPTOMS IN THE DIAGNOSIS OF DISEASES OF CHILDREN.

Among the "single symptoms" which Emeritus Professor Politzer[4] enumerates as in some cases pathognomonic is a *strongly marked nasal or palatal cry.* This is present in, amongst other complaints, syphilitic ozœna, hypertrophied tonsils, and paralysis of the soft palate; but where these can be excluded it affords very strong presumption of retropharyngeal abscess. Dr. Politzer relates that on one occasion he was examining a child when the nurse passed through the room bearing another, four months old, in her arms. On hearing it give this nasal cry he stopped the nurse, but the mother affirmed that the baby was quite well. However, Politzer introduced his fingers and felt the expected swelling. This was incised, and a large quantity of pus evacuated.

THE TREATMENT OF CORYZA.

Surgeon-major G. E. Dobson, in a note in the *Lancet*, May 31, 1884, recommends the following as an effective method of treating this troublesome complaint. About a drachm of camphor, coarsely powdered, is placed in an ordinary shaving jug, which is then half filled with boiling water. The patient, having made a cone (out of a sheet of brown paper or an old newspaper) large enough to surround his face by its wide extremity and the mouth of the jug by its narrow end, proceeds to respire freely, at each inhalation drawing the steam into his nostrils, and at each exhalation forcing it up against the outer surface of his nose and adjoining parts of the face. A two-fold action is produced: the camphorated steam acts internally in a specific manner upon the whole extent of the mucous surfaces, and, externally, produces profuse diaphoresis of the skin covering the nose and sides of the face, there acting as a derivative from the inflamed Schneiderian membrane. The patient should

[3] Revue Médicale, August 11, 1883.
[4] Jahrbuch für Kinderheilkunde, Band xxi., Heft 1.

continue his respirations from ten to twenty minutes, repeated three or four times in as many hours.

A NEW DIVERTICULUM OF THE NASO-PHARYNGEAL SPACE.

Dr. O. Pertik[1] describes a new diverticulum situated in the naso-pharyngeal space. It was discovered in a man about fifty-five years of age, who had died suddenly. On removing the cervical vertebræ and the tissue at the back of the pharynx a fluctuating, bilateral, symmetrical sac was observed, composed of fat and connective tissue, which projected laterally and downward over the upper part of the concave wall of the superior constrictor of the pharynx. Instruments could be passed into it from the lower part of the nasal passage, and it was found, when examined, to be nearly filled with coagulated blood. Two similar cases are reported by Luschka and Zuckerkandel. Dr. Pertik believes that these formations are congenital, and that their effect is to alter the normal resonance quality of the voice.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY, AND HYGIENE.

ALBERT N. BLODGETT, M. D., SECRETARY.

JUNE 7, 1884. The meeting was called to order at eight o'clock, DR. E. M. BUCKINGHAM in the chair.

After presentation of a summary of the report of the previous regular and special meetings of the Section the reports of committees were called for.

The SECRETARY announced that the committee appointed at an earlier meeting to take into consideration the question of the milk supply of Boston had prepared a partial report, which was in the hands of the secretary, who, by request, read as follows: —

PRELIMINARY REPORT OF THE COMMITTEE APPOINTED TO TAKE INTO CONSIDERATION THE MILK SUPPLY OF BOSTON.

The committee appointed at the meeting of the Section on February 27, 1884, "whose duty it shall be to report upon the whole subject of the providing of milk for Boston, and suggest the means of obtaining it pure for the citizens," have attended to that duty, and have held several meetings, at which all, or nearly all, the members of the committee have been present. They have visited the section of country from whence most of the milk supply of Boston is derived, and have endeavored to ascertain the manner in which it is treated at the farm where it is produced, and have followed its history as nearly as possible until it is delivered in the city. The committee has on several occasions had the benefit of the advice and counsel of those interested in the purity of our milk supply, and has considered the question of a change in the present methods of transportation and delivery, and has carefully examined several forms of cans for the transportation and delivery of milk, and has also made careful study and examination of many samples of milk obtained from different sources representing some of the various grades of milk sold for consumption. The committee has been so fortunate as to receive the offer of every facility for the continuance of its work from the office of the State Board of Health, as well as from that of the City Board of Health, and has been promised the assistance of the Milk Inspector of Boston in its efforts to devise a means for improving the quality of milk supplied to the people.

A work of such magnitude as that which has been intrusted to your committee could not be concluded in the limited time since the appointment of the committee, and it is desired at this time to present a preliminary report of progress with the suggestion that the committee be continued and allowed to prosecute its labors, and report to the Section at some future meeting of the Society.

The labor intrusted to the committee seemed legitimately to commence at the source of supply, the farmer's stable, where the cows are housed, and consequently one member of the committee has made a personal inspection of the farms and dairies in several localities. The investigation was made in four towns in Worcester County. It is the usual custom of the farmers after milking one or more cows to strain the milk into the eight-and-a-half-quart cans furnished by the contractors, which, when full, are set in cellars during the winter months, and in warm weather lowered in springs, wells, or put in tubs supplied with running water. A can partially filled in the morning is mixed with enough evening milk, after it is cooled, to fill the can. A letter or mark with chalk on each stopper indicates from whose farm the milk is obtained. Just before the milk is called for by the collector the stoppers are put in place. During the evening it is transported to the railroad station and put on board cars especially designed for this purpose. In the winter a small stove is used to prevent freezing. In the summer the cans are iced with great care. The milk arrives in Boston early the next morning, and is delivered to the distributers during the day.

Many farmers are careless in cooling the milk, and as a result it is returned sour by the contractors. This is nearly a total loss to the farmer, as he receives no pay, and often the cream has been removed.

Many of the cows were very dirty. Their hind flanks were covered with manure an inch or more thick, which must often drop into the pail, and is, no doubt, the deposit so frequently found in the consumer's supply. The contractors often complain to the farmers for not being more careful in this regard.

If a farmer waters the milk it is immediately returned, and to every man who comes to the car it is whispered very privately that Mr. W. has been caught, and a request "not to say anything about it." In a few days all in the town know it, and if the man chances to be a church member his punishment seems to be adequate.

None but "grade" cows are kept for supplying "railroad" milk, and their food is such as to improve the quantity rather than the quality. In the winter English hay, shorts, cotton-seed meal, roots, and occasionally corn meal are fed. In the summer grass and corn fodder.

But very few of the farmers have silos.

The prime defect in the present system of milk supply appears to your committee to consist mainly of two factors, namely, the employment of such a kind of can as admits of being opened without detection,

[1] Arch. für Path. Anat. und Phys. und für klin. Med.

whereby the milk may be variously manipulated in the form of addition or subtraction, or both, and which gives to the consumer a deteriorated quality of milk, as the analyses of the State Board of Health conclusively show, the proportion of specimens which were found to be adulterated amounting to ninety per cent.

The other defect in the present system of supply is the habit, now almost universal, of keeping the milk received on one day until the next morning, thereby adding a considerable amount of time, sometimes as much as twenty-four hours, to the age of the milk when it finally reaches the consumer. This is a disadvantage in another respect, as it exposes the milk to whatever deleterious influences or infective processes may be contained in the place of storage, where it is necessarily exposed to the air in the process of mixing and putting into small cans for family service. The temptation to adulteration which here exists should not be forgotten, and it is at this part of its journey that by far the larger part of all adulteration is committed.

Any practical method of delivery to consumers immediately on the arrival of the milk in the city depots, and of avoidance of the process of mixing and re-canning would seem to offer a remedy for these two greatest dangers to which milk is exposed.

It might be said that it would only be inviting the farmer to adulterate the milk instead of allowing the retail milkmen to do so, but this would be less likely to occur, as any particular dairy could be easily identified, which is not possible under the present system.

Another disadvantage attending the prolonged keeping of milk arises from the necessity of adding some chemical substance to prevent fermentation and souring. This addition may not be directly injurious, but it is an adulteration, and the addition of any foreign substance to milk should be condemned. It is also to be feared that the additions made to milk, particularly that sold in stores, are not always harmless.

The committee has examined several varieties of cans and glass jars for the transportation of milk from the source of supply. The system of glass jars has never been practically tried in this city, but from places where this system has been introduced it was learned that the loss by breakage is very considerable, amounting, on an average, to a complete renewal of the entire stock of jars once in three months. Your committee is unable to find any place where this system has long remained in operation except in the case of certain private individuals who carry on a limited business in milk, and charge an unusual price. This system seems entirely unsuited to the requirements of a general milk supply, and your committee cannot recommend it. A can holding sixty quarts was brought to the attention of your committee, and illustrated by a model. This can is of steel, made without solder, and is of strong and durable character. It is provided with a large opening for cleansing purposes, and may thus always be thoroughly freed from impurities before receiving milk. This can is to be filled at the farm of supply, and when full a cover is placed in the opening and securely fastened and sealed with lead so that it is thereafter impossible to obtain access to the interior of the can until the seal is removed by an authorized person. In this can the milk is cooled and transported to Boston in the same manner as is now done with the ordinary can. The milk can be withdrawn as required, only by inverting the can, when it flows freely from a valve-opening, which closes automatically the instant the milk ceases to flow through it. It is practically impossible to tamper with the contents of this can after the cover is adjusted, and efforts to introduce water by the orifice for pouring out the milk were not successful. Air is allowed to enter the can to replace the milk as this is poured out, by means of a second guarded opening, through which it is impossible to introduce any foreign substance whatever. The advantages claimed for this can are its imperishable nature, its ease of cleansing, its perfect protection of the milk from manipulation or contamination, the thorough mixing of the milk at every withdrawal by the necessary inversion of the can, the impossibility of removing the cream from the milk, and a saving of several hours of time in the age of the milk when it is delivered to the consumer.

The objection was raised that the adoption of this can would preclude the possibility of obtaining the milk of one cow separately for the use of infants or invalids. The committee considered this point carefully, and came to the conclusion that this constituted no objection, inasmuch as the milk now furnished to the people of Boston is almost invariably brought to the city in large tin cans, and is put into service cans for family use at the milk sheds after its arrival in Boston. It is, therefore, practically impossible to secure the milk from one single cow for any purposes whatever. Your committee also came to the conclusion that one cow's milk presented no advantage to recommend it above the mixed milk from a dairy of several cows. Indeed, the advantage seemed to be on the side of the mixed milk, as this constitutes a protection to a certain extent against the perturbations of health and of the quality of milk supplied by any one animal.

Your committee also desires to point out the fact that the majority of people taking milk from milkmen are not acquainted with the varying character of this secretion at different times of year and under different conditions of health in the cow.

During the months when the cows are fed on hay the milk is generally much paler and somewhat thinner than when the cows are at pasture. By demanding at all seasons of the year a quality in milk which exists in it at only one season the people unconsciously encourage adulteration of milk, and thus defeat their own best interests.

With the hope of placing a supply of pure and wholesome milk within the reach of the inhabitants of the poorer parts of the city, and especially of sick children and invalids, your committee would suggest the establishment of "milk stations" in accessible and well-known localities, possibly in connection with the district dispensary establishments, or at certain drug stores, to which the poorer people, and particularly the sick, might be referred by physicians or others, and by means of a ticket or voucher obtain a supply of pure milk at a cost within their means, instead of buying, as is now too often the case, milk which has been diluted sometimes to the extent of sixty per cent.

It is in the poorer parts of the city that the greater proportion of adulterated milk is to be looked for, and therefore it forms the supply of those who most need a pure and wholesome article. There can be but little doubt that the rate of mortality among children might be materially affected if it were possible to furnish pure and fresh milk to the inhabitants. The "depots,"

as suggested above, seem to your committee to be a step in this direction.

Signed by the committee.

HENRY O. MARCY, *Chairman.*
E. W. CUSHING.
LLOYD F. ABBOTT.
HENRY J. BARNES.
ALBERT N. BLODGETT, *Secretary.*

The report of the committee was accepted, and, in accordance with the suggestion contained in the paper, the committee was continued, in order that its labors may be prosecuted still further, and the utmost benefit be derived from the thorough investigation of an important branch of domestic supply, upon which the lives and health of a large proportion of our population are more or less directly dependent.

The hour being already somewhat late, it was voted that the reading of the papers appointed for this evening, by Dr. F. C. Knapp, on "Observations on the Cutaneous and Tendon Reflexes," and Dr. F. Minot, on "Three Cases of Distended Gall-Bladder," be postponed to the next meeting. The readers having expressed their approval of this arrangement, and there being no further business before the Section, it was voted to adjourn, at 9.15 o'clock.

Medical and Surgical Journal.

THURSDAY, JULY 31, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

ELECTRIC NEUROSIS.

THE public exhibitions which have been given of late in some of our large cities of Lulu Hurst, in which it is claimed that the girl is able to exert upon inanimate objects a force, which while not muscular, is able to oppose and overcome muscular force exerted against it, have attracted popular and professional interest. And while it is true that those best qualified to judge who have witnessed these exhibitions have been generally of the opinion that the force exercised by Miss Hurst is capable of satisfactory explanation as being the product of strong muscles, trained with especial reference to overcoming by sudden and unexpected movements the steady and even attentive resistance of an opponent unpracticed in the best way to meet these sudden onsets, yet it is of interest to learn in this connection of well-observed cases of real electric force disengaged by the human body, — involving nothing especially occult or mysterious either. In *Le Progrès Médical* (July 5th) a short article by Féré speaks of some of these cases.

In the first case described in this paper, a woman of neuropathic constitution, twenty-nine years old, with perversions of appetite, ovarian excitability, etc., had noticed from girlhood the production of sparks in her hair when it was combed, but this common phenomenon during the two years before she came under Féré's observation had increased in intensity. Light objects clung to her fingers, and the hair not only gave forth sparks on being combed but obstinately stood up on end, each hair repelling its neighbor. When her linen approached the skin it caused a luminous crepitation, and her vestments adhered strongly to her body; sometimes this adhesion impeded her movements. These phenomena were noticed by Féré on several occasions. A few strokes of the hand on a napkin spread on a piece of wooden furniture caused the stuff to adhere strongly to the wood, and from it sparks could be drawn a centimetre in length. The most intense electric discharges followed lively moral emotions, for instance when she had just heard a piece of music which had deeply moved her. The crackling sounds were then perceived all over the body, especially in the legs, and a disagreeable pricking sensation was produced. Frosty weather favored the electric phenomena, but damp days hindered them; a change in humidity could even be predicted several days in advance, from modifications in the electric tension. A high electric tension corresponded with a state of excitation clearly appreciated by the patient herself; but in wet weather when the tension diminished there was general lassitude.

This patient, who was ill nourished and anæmic, had a marked œdematous infiltration of the legs, which possessed the peculiarity of nearly disappearing in dry weather, and in damp days increasing so as almost to prevent locomotion. The loss of electricity was met in the treatment of the case by directing silk clothing, and in moist weather she was given an electric bath of ten minutes daily, with relief to the sensation of fatigue.

Other cases have been reported. Mussey [1] speaks of a case of a woman of thirty, of nervous temperament, who, during an aurora borealis, was suddenly charged with electricity, whose presence showed itself by sparks when the woman, by chance, passed her finger over the face of her brother. This phenomenon lasted with variable intensity for two months and a half. In the most favorable conditions she sent from her finger to a copper ball four sparks a minute an inch and a half long.

Other cases are recorded in which electrical phenomena, especially noted in the hair, seemed to have a relation to mental irritation, to neuralgic attacks, and other manifestations of nervous derangement. So long ago as 1846 Arago described to the *Academie des Sciences* a young girl who appeared to him to have the power of attracting certain light bodies and repelling others without touching them, but these facts were not reproduced before the committee of the Institut. It is, perhaps, needless to say that every such claim should be subjected to the most searching investigation before its validity is allowed. The ability of hysterical women to fool the public mind is very

[1] Extraordinary Case of Animal Electricity. American Journal of Medical Science, 1837, vol. xxi., p. 377.

great. We confess to a feeling of suspiciousness of people of any class who "attract light objects to their fingers." And we suspect that most of the influence exerted upon surrounding ponderable matter by women exhibiting themselves either for fame or for money emanates from a contraction of the *flexores digitorum*.

TREATMENT OF THE VEGETAL PARASITIC SKIN DISEASES.

WHATEVER conflicting views may be held respecting the rôle of microphytes in internal pathology (and certainly the germ theory of contagious diseases seems every day to be receiving fresh support), there are certain communicable skin affections which by common consent of dermatologists are attributable to the irritation caused by parasitic fungi. The proof that the diseases in question are occasioned by the presence of the fungi is such as to satisfy every scientific requirement. The presence or absence of the parasite always attends presence or absence of the pathological condition; the disease can be induced by topical communication of the spores of the microphyte, as Gruby found with reference to the *Tricophyton tonsurans* more than forty years ago; eradicate the fungus and you eradicate the cutaneous affection, as has been shown in innumerable instances; finally, the spread of the eruption varies concomitantly with the extension of the fungus.

The phyto-parasitic diseases are Trichophytosis, or ringworm, due to the lodgment and growth of the *Tricophyton tonsurans;* Tinea favosa, or favus, caused by the *Achorion Schonleinii;* Chromophytosis, or Pityriasis versicolor, dependent on the germination and development of the *Microsporon furfur*. Four varieties of Trichophytosis are described, which recognize the same cause but differ in appearance by reason of their locality, namely, Trichophytosis-capitis, barbæ, corporis, and genito-cruralis. The vegetal parasites are microscopic organisms, akin to bacteria and vibriones, presenting themselves under the aspect of cells, isolated or multiple, which latter are often united end to end, in the form of straight or flexuous tubes. They are constituted of three principal parts: mycelium, spores, and receptacle. The first represents the body of the organism, the second are the reproductive elements, the third is composed of filaments springing from the mycelium, and which bear the spores. But little is as yet really known as to the natural history of these cryptogamic formations; they are undoubtedly polymorphous. Hallier believes that the human phyto-parasites belong to a small number of species which are capable, under different conditions of culture, of undergoing profound modifications. Their typical condition when grown where there is free access of air is that of *moulds;* the state of *achorion, leptothrix, torula, tricophyte*, etc., results from privation of air or of light.[1]

As for the habitat of the cutaneous parasites, the microphite of chromophytosis luxuriates among the inner epidermic cells; its spores and mycelium do not invade the hair follicles and hairs, which are the favorite sites of the achorion and trichophyton tonsurans.

The treatment of these parasitic skin diseases is one of great simplicity; as they arise from local, not general, causes (except so far as debilitated conditions of the organism favor the invasion and ravages of the fungus), topical measures are generally sufficient for a cure. Unfortunately, however, it is not always easy to meet the indication of "bearding the monster in his den," by a suitable parasiticide. While the habitat of the microsporon that causes chromophytosis is sufficiently near the surface to be accessible to lotions or ointments containing sulphur, mercury, chlorine, etc., and the same may be said of the trichophyton that causes ringworm of the body, the affections of the hairy scalp and beard, and tinea cruris, the so-called eczema marginatum, are much less manageable. In tinea of the scalp and beard the mycelia and spores of the parasite penetrate deeply the hair follicles, and even invade the roots and fibres of the hair; the infiltration is always distant from the surface, and hence is not easily reached. Therefore in order to destroy the fungus *in situ* epilation is necessary. This, to be effectual, must be done thoroughly, a little at a time, every hair being carefully plucked out by the roots with the epilation forceps; then a solution of carbolic acid or of corrosive sublimate (one grain to the ounce) should be applied. The solution readily penetrates to the follicles through the track left by the hairs. Instead of the corrosive sublimate solution Vlemingk's solution of sulphur and quick lime may be used after epilation. The principal discouragements arise from imperfect removal of hairs, which, owing to their brittleness, easily break off during extraction, leaving the stumps remaining with the roots and follicles to continue the disease. In these cases epilation will have to be repeated as fast as the hairs grow out again. In cases where thorough epilation has proved impossible or inefficacious it was several years ago proposed by Dr. Alden Smith to produce an artificial kerion by croton-oil inunctions, thus instituting a severe inflammatory process by which the fungus is destroyed. This practice has been adopted with varying success by dermatologists in all parts of the world. Instead of croton oil, goa powder and ointment of chrysophanic acid have been used with the same intention. Dr. Robert J. Lee, in the *British Medical Journal*, July 21, 1877, was one of the first to protest against this mode of treatment as being unnecessarily severe. After a long experience with inveterate cases he found a combination of olive oil, sulphur, and carbolic acid to be the most satisfactory. One drachm each of precipitated sulphur and oxide of zinc, with sixteen grains of crystallized carbolic acid, is added to one fluid ounce of sweet oil. This must be rubbed in every five hours with a sponge or brush, the head being washed with castile soap and warm water every night and morning before the application of the carbolized oil. He regards this preparation as sufficiently penetrating to destroy spores which exist under the horny layers.

[1] Fournié, Applications des Sciences à la Medecine, Paris, 1878, page 668.

Dr. Morris Smith, in the *Lancet*,[1] strongly advocates the use of a solution of thymol in chlorcform (thymol, 3ss, chloroform, 3ij, olive oil, 3vj) as being the very best antiseptic and parasiticide of which he has had experience. By adding coloring matter (asphalt) to this solution he had had ocular demonstration that the dye had penetrated the follicles (the subject on which he experimented and from which portions of the skin were taken for examination being a dog). The oil in the above prescription is added to arrest the evaporation of the chloroform and to prevent it from acting as an irritant. By the use of this preparation, he says, "the disease is more quickly cured than by any other method I have ever tried." The oil should be well rubbed in after first washing the diseased scalp with soap and water. After the treatment is commenced neither soap nor water should be again used.

In the July number of the *Journal of Cutaneous and Venereal Diseases* the subject of the treatment of the vegetable parasitic diseases is ably discussed by Dr. Shoemaker, who insists first on attention to the constitutional condition. If debility exist tonics and good food are demanded. To lessen the ravages of the parasite and destroy it he would first interdict water, frequent use of which favors the development of the parasite. The diseased surface should be cleansed every day with sulphuric ether or with a mixture of equal parts of ether and alcohol with a few grains of thymol. Another good antiparasitic is equal parts of ether and alcohol with boracic acid. In trichophytosis capitis he first procures isolation of the patient. The spread of the contagion may be prevented or lessened by washing the parts in ether or an alcoholic solution of borax. This should be followed by oiling the hair and scalp with a solution of thymol (ten to twenty grains to an ounce of sweet oil). He orders the seat of the eruption to be sponged with a weak alcoholic solution of thymol, borax, naphthol, or corrosive sublimate. To the surface thus cleansed he rubs in a fifty per cent. solution of boro-glyceride till the whole scalp seems saturated with it. Borax is one of the most efficient antiparasitic agents, and is mildly astringent and soothing. Glycerine penetrates and carries the substance into the follicles to the parasite; it also withdraws water from the tissues, thus depriving the fungus of one of its main elements of development. The solution should be applied night and morning with a little sponge or mop, and should be well rubbed into the follicles with the tips of the fingers.

Oleate of copper is excellent where the above means fail. It has the power of deep penetration to the parts, especially the follicles. The ointment is made by blending one part of oleate of copper with nine parts of lard. A small piece of this ointment should be rubbed over the affected surface night and morning till all traces of the disease have disappeared. A ten per cent. ointment of oleate of mercury has also given good results.

Rubbing in croton oil to produce an artificial Kerion is only to be resorted to in very chronic cases where all other means fail.

The same treatment holds for *trichophytosis barbæ*. As for trichophytosis corporis, mild forms are, in the writer's experience, readily cured by the use of the thymol, naphthol, and corrosive sublimate solutions, while obstinate cases readily yield to the copper oleate.

In favus the oleate of mercury is generally sufficient to effect a cure if well rubbed into the scalp after the necessary epilation and removal of the epidermal scales and cups.

FEMALE PHARMACISTS.

AMONG the new means of livelihood which women have claimed for themselves at the present day is that of pharmacy. At Louisville, Ky., a school has been established for giving instruction in this calling. It has just completed the first year of its existence and has graduated a few students. It had its origin in a demand for special educational facilities by certain women, already engaged in the business, and others desiring to enter thereon. While the School is designed especially for the instruction of women, yet male pupils are admitted on application, provided there is an excess of room after the wants of women are supplied.

The dispensing of drugs and the compounding of prescriptions is an occupation, so far as we can see, within the physical capability of women. While the calling of the pharmacist involves great responsibilities, yet they are such as can be mastered by a person of steady hand, clear eye, sober and accurate habits, who has in addition to these qualifications a proper training in practical chemistry and in pharmacal manipulation. These latter elements are now offered in the Louisville School, and we have no doubt that in so far as the former ones are present in the students who apply for instruction, the results will be satisfactory both to them and the public.

One thing, however, should be borne in mind by women entering upon this as well as upon other callings formerly limited to the other sex. In the evolution of modern society women have changed their relation to the world's work. No longer do they, as in the days of chivalry, from on high —

> "Rain influence and judge the prize
> Of wit or arms."

Far be it from us to say that woman's present position among the world's workers is one of less inherent dignity than that she formerly held. But the point to be emphasized is this, that having made the change, having come down into the soil and turmoil, she can no longer expect to receive the chivalrous devotion which was the accompaniment of the feudal institution. Work is a leveler, and distinctions of sex as well as of class disappear before it. Men are not likely to abandon the callings which they have been used to follow. In pharmacy as in everything else they are already in the field. Competition everywhere is sharp; in it the weaker always go to the wall and the stronger survive, whether they be men or women. The

golden rule is the most favorable code that women can hope for, and if they always are treated in accordance with that they will be faring better than most men. Any special consideration by virtue of their sex they must not expect. Employers will not pay for a month's work if there have been only twenty-eight days of service, and if in the competition of any calling woman suffers because of her physical limitations, she must accept the fact of those limitations and not quarrel with their necessary consequences.

PARALDEHYD.

THIS hypnotic, which is proposed as a substitute for chloral, has been somewhat used of late. Like chloral it is not useful for the relief of pain, but only to promote sleep in insomnia. It is a liquid with an agreeable, somewhat ethereal (?) odor and unpleasant taste; it is, however, less irritating than chloral. In some instances only it is said to have caused nausea. In diseases of the stomach or in advanced phthisis it is contra-indicated.

It does not exert much influence on the respiration or on the circulation, which would suggest that it may be more safely administered in cardiac affections than the more common hypnotic chloral. The dose of paraldehyd is rather larger than that of chloral, and it must be increased as the system becomes tolerant of it. At present it is much more expensive than chloral, but this disadvantage would doubtless be readily overcome should it prove to have any material advantages over its older rival. It may prove to be a useful substitute for, or alternate with, chloral in cases where that drug is not found to agree with the patient, or when it is desired to interrupt from time to time its long continued use.

MEDICAL NOTES.

— The *Dublin Journal of Medical Science*, speaking of the use of vaseline to prevent loss of alcohol from specimen jars, says that in a paper with this title, by Prof. Burt G. Wilder and Dr. Simon H. Gage, of Ithaca, N. Y., attention was called to the fact that the petroleum preparation termed vaseline was known to be practically unaffected by ordinary temperatures and by most substances. In the *Journal of the Chemical Society* for July, 1882, page 785, it was said to be sparingly soluble in cold, strong alcohol, and completely in hot, but to separate out on cooling. After trying various substances — wax, paraffine oil, and glycerine — with but partial success, the use of vaseline was suggested by the two authors independently and nearly at the same time. The experiments tried last spring indicated that during three months, at ordinary spring and summer temperatures, there was no appreciable loss of ninety-five per cent. alcohol from glass phials or jars, whether upright or inverted or on the side, provided the corks were smeared on the bottom as well as on the side. Ground-glass stoppers were anointed and firmly inserted, and the rubber rings of fruit jars and the specimen jars, made by Whitall, Tatum & Co., were coated on both sides and the covers well screwed down. The authors had also used the vaseline for preventing the loss of other liquids, including chloroform and oil of turpentine, as a lubricator of drawers, and to prevent the sticking of the covers or stoppers of cement phials, and for the prevention of rust upon steel instruments.

— The *Pacific Medical and Surgical Journal* has been consolidated with the *Western Lancet*, and is to be edited by Dr. Whitwell, who is a graduate of Harvard, and should be well fitted for the position which he is to assume.

— M. Rigaud, in the *Journal de Therapeutique* speaks favorably of collodion as a remedy for the pleuritic pains often so harassing in phthisis. It is applied in successive layers till a sort of cuirass is formed, solid enough to withstand movements of the chest. If a split occurs it should be immediately repaired by a new application.

— In its application to carious teeth, remarks *Progrès Médical*, creosote is often inconvenient in consequence of its fluidity producing ill effects upon the mucous membrane of the mouth. This may be obviated by giving to it a gelatinous solidity by adding ten parts of collodion to fifteen of creosote. This, besides being more manageable than liquid creosote, also closes up the orifice in the tooth, preventing the accession of the air to the dental nerve.

— Dr. Betz (*Memorabilien*, January, and *Medical Times*, June 11th) strongly recommends nitrate of silver in spinal irritation as a means of relieving the attendant pain whatever may be its primary cause. A solution of one part of nitrate of silver to one hundred of alcohol is thoroughly applied twice a day not only to the painful parts, but also for some distance beyond these, and, when necessary, along the whole spinal column. The liquid penetrates quickly, and soon dries up, producing an agreeably cool sensation, and very seldom gives rise to any irritation of the skin. This painting of the parts will have to be continued for weeks or even months, especially if there is any disease of the spine itself present.

— A report was read before the Sub-Section on Public Health of the Academy of Medicine in Ireland (*Medical Press*, July 9th), by Dr. Cameron, on antiseptic experiments in the vaults of St. Michan's Church, Dublin, celebrated for their antiseptic properties. Bodies dry up in a desiccated mass rather than decompose when deposited in these vaults. The author placed an infusion of melon in Tyndall's tubes, and having submitted both to a high and prolonged temperature so as to sterilize the liquid, he placed a number of them in a vault of the church which seemed to possess the greatest antiseptic properties. The tubes were deposited with great caution, and in such a way as to occasion the least possible disturbance of the atmosphere. The extremities of the tubes were broken by means of hot forceps, and the vault was kept locked up for six weeks. They were then removed from the vault. Seven of the tubes presented no change, but in the remaining five there was great

turbidity, owing to the development of mycelium, etc. In the case of the liquid kept in the unbroken tubes at the laboratory of the Royal College of Surgeons no turbidity was noticed in their contents. On nipping ends of the tubes of those kept in the laboratory and the sound ones brought from the mortuary vaults turbidity set in under forty-eight hours. The author did not venture to draw any positive conclusion from these experiments, but their results seem to show that the preservation of the liquid was due to the great freedom from dust which he noticed in the vault. Franklin, the reader remarked, had found that in the higher Alps organic infusions remained for a long time freely exposed to the air without undergoing decomposition, a fact attributed to the freedom of the air at great altitudes from dust, which, of course, included germs of various kinds.

— A correspondent of the *Medical News* says that an operation of enterotomy was recently performed upon a Pittsburgh lady of wealth. The surgeon removed four inches of the small intestine, uniting the divided ends by sutures. She recovered. He charged $1000 for the operation and twelve days' attendance. As payment was refused he brought suit. The jury gave a verdict for $330, which was thus arrived at: Each put down the amount he would allow. They then divided the aggregate sum by twelve, and thus reached the verdict. In some other similar cases that we have heard of it would seem as if each juryman must have divided the figures of his individual estimate by twelve before averaging.

PHILADELPHIA.

— Prof. Robert E. Rogers, who held the chair of chemistry in the Jefferson Medical College, has resigned.

Miscellany.

A STATEMENT IN REGARD TO THE CHARGE OF NEPOTISM AT THE MASSACHUSETTS GENERAL HOSPITAL.

IT is sometimes said that the nominations of the visiting physicians and surgeons for house pupils at the Massachusetts General Hospital are influenced by nepotism, and that a connection of any member of the staff is sure to get the appointment he wants, to the exclusion of all other candidates. The list of appointments for house pupils both on the medical and surgical services of the hospital for eleven years from 1874 to 1884 inclusive, obtained from a report recently made by a committee of the Board of Trustees, — at whose request this publication is made, — tends to show how entirely without foundation such statements are.

It appears that out of forty-four appointments on the surgical side five were of gentlemen in some degree connected with surgeons who had at some time been upon the hospital staff.

Out of twenty-two appointments on the medical side three fall into a similar class.

On the surgical side the appointments were: A. T. Cabot, 1875; George G. Hayward, 1879; W. D. Hodges, 1880; John Homans 2d, 1881; Edward Reynolds, 1884.

On the medical side there were: J. J. Minot, 1877; V. T. Bowditch, 1878; Henry Jackson, 1883.

Of the surgical appointments three, Messrs. Hayward, Homans, and Reynolds were not connected with any member of the staff which nominated them. Mr. Hayward's grand uncle and the grandfathers of Messrs. Homans and Reynolds had been upon the staff, probably before the birth of those gentlemen.

On the medical side Messrs. Bowditch and Jackson had no connections upon the nominating staff. There remain, then, out of sixty-six appointments three gentlemen who were connected with members of the staff nominating them. But there is no reason to believe that these gentlemen were nominated for any other reason than merit.

The allegation that when a relative of any member of the staff applies for a position he is sure to get it is further disproved by the fact that several instances have occurred where such relatives have failed to obtain the places applied for, because the staff did not consider them the best fitted for the place.

The object of the Trustees is to appoint as house pupils the best available men. They attach the greatest importance to the nominations sent them by the staff; but they regard these nominations as only one (perhaps the most valuable) among several sources of information concerning the candidates.

It would be a mistake to suppose that those appointments are offered as prizes to the best scholars, or to those who pass the best examination by the staff. Those examinations are not intended to be thorough tests of knowledge. Candidates who have maintained high rank at the Medical School, and who are successful at the examinations of the staff, have secured important advantages. But besides good scholarship other qualifications are to be considered, such as dexterity, good character, good manners, tact, the power of getting on with other men. In short, all the qualities, moral, intellectual, and physical, which go to make the successful physician or surgeon, the Trustees try to obtain in the house pupils. If those qualities should be found in the highest degree in candidates who were also near relatives of members of the staff it would be the duty of the Trustees to appoint them.

THE ORGANIZATION OF AN INTERNATIONAL SCIENTIFIC ASSOCIATION.

MR. CHARLES S. MINOT writes in *Science* (July 25th), regarding the movement on foot to secure the establishment of an International Scientific Association, that there is now in circulation for signatures a request supported by some of the leading scientific men of America, and addressed to the two national associations which meet on our side of the ocean this year. This request is to the effect that the two bodies shall consider the advisability of forming an international association.

Mr. Minot enumerates some of the advantages in an association of this sort, and adds: —

"As regards the special occasion of founding the new organization, the advocates of doing so in America this summer maintain that another opportunity is not likely to soon re-occur so favorable as will be af-

forded by the meeting of the British Association in Canada, followed immediately by that of the American Association in Pennsylvania. If the scheme is carried out, it will, in fact, be the legitimate and anticipated culmination of a movement of which the coming to America of the British Association is one part. In 1881 the proposal was made that the American Association invite the British to America. This was actively discussed, and finally it was determined — largely, I believe, from motives of real modesty — to postpone the invitation, and issue instead a large number of special requests to individuals to attend from abroad the meeting of our Association at Montreal. This duty fell to the local committee of Montreal in 1882. The large number of foreign visitors who came revived the hope that the British Association could be induced to come over as a body. The matter was then independently taken up by the Canadians, and pushed generously and eagerly towards the great success which every one now anticipates for the gathering at Montreal. From the first it has been understood that if the original enterprise, which was in many ways so full of difficulty, should be brought to a successful issue, then the still greater enterprise should be broached, and the foundation of a permanent international association be attempted.

"It is hoped that the British Association will take some action in the matter. It has been suggested that a committee with powers might be appointed to confer with the American Association at Philadelphia. The organization of the latter body is such that no further official action on its part is possible until the time of meeting itself; but there can be no doubt as to the cordiality with which any proposal emanating from the British Association will be received. At present no definite plans have been formed, as it has been felt that public discussion was necessary before making any decision; but, as it is advisable to gather as many suggestions beforehand as possible, I shall be glad to correspond with any one interested in the proposal."

A REMARKABLE EPIDEMIC OF SORE THROAT ORIGINATING IN A MILK SUPPLY.

IN the *Practitioner* for June appears an account of an epidemic of sore throat occurring in February last in Dover, England, distinctly traceable to a milk supply from cows suffering from aphthous fever (foot and mouth disease). In four days 188 persons were attacked by a malady whose leading symptoms were uniform in the whole series of cases. These symptoms were local inflammation of the throat, accompanied by enlargement of the lymphatic glands of the neck, vesicular eruptions preceding and accompanying the inflammation. During the week ending February 9th 205 persons were attacked, all of whom obtained their milk supply from one particular dairy.

The houses in which these people resided were distributed in forty-two different streets in the town, widely separated from each other.

In nineteen of these streets (or nearly half of the whole number) every house supplied by this milkman was invaded by the epidemic, whilst, with one or two doubtful exceptions, no other cases could be heard of in the same streets, at any rate none of sufficient gravity to require the services of medical men. Thus the striking fact was exhibited of an exact correspondence between the milk supply and the houses invaded by the epidemic.

In the remaining twenty-three streets where this milk was delivered, out of eighty-six houses supplied fifty-one were invaded by the disease.

The number of persons attacked in each house stricken averaged 2.5 per house.

In thirty-one houses there was only one case in each; in twenty-one houses, two cases in each; in fifteen houses, three cases in each; in seven houses, four cases in each; in five houses, five cases in each; in three houses, six cases in each; in one house, seven cases; and in another nine.

The marked correspondence between the victims of this epidemic and the customers of a particular dairyman attracted attention, and investigation was made. He obtained his milk from a dairy of his own in Dover and three farms in the country. From the former source he furnished a special supply to a few customers in separate cans. In one case it was found that a gentleman and his wife who used milk brought thus in a sealed can escaped the disease, while the servants in the same house, using the mixed milk, were attacked.

At one of these establishments in the country it was found that aphthous fever had broken out amongst the stock on January 14th, and that milk from some of the affected cows was delivered to the Dover dairyman, and, after being mixed with other milk, distributed to his customers. Moreover, it was from this infected farm alone that the Dover dairyman obtained the supply of cream furnished to his customers.

At the beginning of the inquiry it was stoutly denied that any of the milch cows had suffered from disease, and a certificate from a veterinary surgeon and inspector to this effect was obtained and published. Recourse was had to the police, and the truth gradually oozed out, until the facts, as above stated, were established beyond dispute; then the farmer not only admitted the fact of the disease amongst the milch cows, but confessed to the sale of their cream and milk in Dover not only to the dairyman whose milk was specially implicated, but also to another milkman, on two separate occasions, amongst whose customers a second simultaneous outburst occurred. Thus a second experiment was performed with this tainted milk amongst another set of individuals with like results to the first, contributing (if such corroboration was necessary) additional evidence of the presence of poison in the milk supplied from the infected farm.

The diseased cows and stock, which were clearly shown to be suffering from the symptoms of the foot and mouth disease, were kept in low, close sheds surrounding a small yard, which was full of decaying manure, rotting turnips, and the infected excreta, so that the specific poison, after elimination from the animals, would, instead of living structures, have for its pabulum decomposing and putrefactive organic matter, swarming, doubtless, with the bacteria attending these changes.

In one case personally observed by the reporter of the epidemic this milk administered raw to a dog produced a blistered and inflamed condition of the buccal and labial mucous membrane, and inflammation of the skin and cellular tissue between the toes of one foot terminating in suppuration.

In the human subjects attacked the vesicular erup-

tions were followed, either by a raw, red, œdematous appearance of the mucous membrane or white patches, and the ulcers which supervened assumed, in many instances, a chronic character, with thick, puckered edges, and were a long time in healing.

When the inflammation of the tonsils went on to suppuration recovery was much slower than after common quinsy, and the enlarged cervical glands remained tender, red, and swollen long after the throat symptoms had subsided, resembling in this respect the sequelæ of scarlet fever. Erysipelas and purulent formations were concomitants also of the epidemic. In some instances the feet of those who suffered were swollen and painful, simulating rheumatism, and in one case eczema occurred between the toes of the feet, the affection being accompanied with very fetid exhalation.

A fatal termination resulted in the cases of two children, who had very bad throats and mouths, with the extension of the disease, in one case, to the respiratory tract, their deaths being, in the opinion of the medical attendant, due to the poisonous effects of the milk.

Two persons who labored under chronic kidney disease were respectively attacked with sore throats, and died on the same day, other people in the same houses suffering also from the epidemic sore throat.

In one house three persons were attacked, on the 4th February, with sore throat; one of these was a servant girl, who was sent home, and seen by the hospital surgeon on the 9th at twelve A. M., and died at four P. M. Mr. Wood gives the following history of the case: —

"F. S., attacked five days previously with sore throat and pains in the limbs, complained on the 8th of great pain in the epigastric region and dyspnœa. There was a purple-red patch on the left cheek extending to the nose. At three P. M. on the 9th she passed into a state of coma, and died at four P. M."

Mr. Wood says this was an obscure case, but thinks it possible that it was one of blood-poisoning.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 19, 1884.

Deaths reported 3232 (no reports from New Orleans, Buffalo, Pittsburg, and Milwaukee): under five years of age, 1883; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases), 1301, diarrhœal diseases 984, consumption 317, lung diseases 160, diphtheria and croup 89, measles 53, typhoid fever 43, scarlet fever 39, whooping-cough 37, cerebro-spinal meningitis 20, malarial fever 20, puerperal fever 10, small-pox one. From *typhoid fever*, Philadelphia 12, New York and Chicago five each, Boston four, Baltimore and Nashville three each, Brooklyn, St. Louis, Cincinnati, and District of Columbia two each, Lowell, Lawrence, and Chicopee one each. From *scarlet*

fever, New York 11, Philadelphia six, Baltimore and District of Columbia three each, Brooklyn, Chicago, Boston, St. Louis, and Cincinnati two each, Providence, New Haven, Lawrence, Springfield, Gloucester, and Natick one each. From *whooping-cough*, New York 10, Brooklyn eight, Philadelphia six, Boston five, Baltimore three, Nashville, Worcester, Cambridge, Lynn, and Brockton one each. From *cerebro-spinal meningitis*, New York three, Philadelphia, St. Louis, and Providence two each, Chicago, Baltimore, Charleston, Worcester, Fall River, Lawrence, and Springfield one each. From *malarial fevers*, New York eight, St. Louis four, Baltimore three, Brooklyn two, Philadelphia, Nashville, Lynn, and Chicopee one each. From *small-pox*, Philadelphia one.

In 156 cities and towns of Massachusetts, with an estimated population of 1,383,104 (estimated population of the State 1,955,104), the total death-rate for the week was 18.58 against 17.68 and 15.35 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,762,354, for the week ending July 5th, the death-rate was 19.5. Deaths reported 3279: acute diseases of the respiratory organs (London) 231, diarrhœa 175, measles 126, whooping-cough 103, scarlet fever 61, fevers 46, diphtheria 25, small-pox (London 30, Liverpool three, Sheffield two, Hull one) 36. The death-rates ranged from 13.4 in Brighton to 26.1 in Huddersfield; Birmingham 15.7; Blackburn 17.9; Bradford 19.2; Leeds 19.9; Leicester 18.9; Liverpool 20.8; London 19.6; Nottingham 22.4; Sheffield 19.4. In Edinburgh 18.2; Glasgow 25.9; Dublin 21.

For the week ending July 5th, in the Swiss towns, there were 32 deaths from consumption, lung diseases 26, diarrhœal diseases 20, typhoid fever six, diphtheria and croup four, whooping-cough one, puerperal fever one. The death-rates were, at Geneva 16.3; Zurich 5.9; Basle 13.9; Berne 18.9.

The meteorological record for the week ending July 19th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

A CASE OF ACUTE HYDRAMNIOS, WITH REMARKS ON THE PATHOLOGY OF THIS AFFECTION.[1]

BY CHARLES M. GREEN, M. D.

On March 9, 1883, Dr. J. R. Chadwick was consulted by an American woman, twenty-nine years of age, whose history was briefly as follows: She had married at the age of nineteen and, in her ten years of married life, had borne five children in rapid succession, namely, in 1875, 1876, 1878, 1879, and 1881. The children were all girls and weighed at birth from eight to ten and one fourth pounds: the labors were all natural. The mother suckled her last baby once a day for four months, when the catamenia appeared and recurred regularly until October 27, 1882, at which date her last period ended. A month later she began to have nausea and vomiting, which symptoms continued with considerable severity until early in March, 1883, since which time she had rarely vomited but once a day. About the middle of February she thought she felt fœtal movements and she had several fainting spells. Believing herself at this time about four months pregnant she thought she was larger than she ought to be: two weeks later, that is about March 1st, the abdomen began to grow rapidly larger in size, and thinking something must be wrong with her the woman sought advice. She was below the medium height and of slender form. The abdomen was symmetrically enlarged to the usual size at the end of the eighth calendar month of pregnancy: the parietes were tense, and the superficial veins well marked. There was tympanitic resonance in the loins and over the epigastrium, elsewhere the abdominal percussion note was flat. Palpation revealed a well-marked fluctuation wave in all directions, stopping short however of the tympanitic region, and showing, as Dr. Chadwick subsequently pointed out to the writer, that the intestines were not floating in the fluid; in other words, that it was not a case of ascites. On vaginal examination the introitus was seen to be of deep violet hue: the cervix was soft, long, and funnel-shaped. No fœtal parts were felt by vagina; but by abdominal palpation Dr. Chadwick felt fœtal parts so remote from each other as to warrant in his mind a surmise of twin pregnancy. No fœtal heart sounds were heard; but the uterine souffle was plainly audible.

On March 12th the case was seen by Drs. W. L. Richardson and C. M. Green in consultation with Dr. Chadwick. The tumor had increased in size, and the patient was suffering from distention and pain in the right side and back. The twenty-four hours' urine amounted to only fifteen ounces, its color was high, specific gravity 1.030, and there was a trace of albumen. Ballottement revealed the presence of a small fœtus. The consultants agreed with Dr. Chadwick in the diagnosis of acute hydramnios, and the patient was placed by him under the care of the writer.

On March 13th the circumference of the abdomen, measured on a level with the umbilicus, was 36.5 inches. Inunction of the abdominal wall with oil and the application of a swathe were advised; and tinct. digitalis and tinct. ferri chloridi were ordered for both their tonic and diuretic effects. Sedatives were also employed. Six days later the abdominal circumference, measured as before, was 39.0 inches, an increase of 2.5 inches; and the distance from the ensiform cartilage to the pubes was 16.5 inches.

On March 21st the patient was found in great distress: she could assume no position in which she was comfortable, she had had no refreshing sleep for several days, narcotics seeming only to deaden her sensibilities. She could take no solid food, felt worn out, and expressed herself as feeling as if she would burst. The twenty-four hours' urine during the past eight days had varied from ten to twenty ounces, the daily average being less than a pint. I determined to induce labor, and at 10.30 P. M. of the same day, with the kind assistance of Drs. Chadwick and J. W. Farlow, I proceeded with the operation. At this time the abdominal girth had not increased above 39.0 inches; but the distance from the ensiform cartilage to the pubes had increased from 16.5 to 18.0 inches: the pulse was 96; the temperature, 98.3° F. The cervix was soft and patulous, the os internum admitting two fingers. A new, English gum-elastic catheter, with its stylet sharply bent about an inch from the tip, I passed between the uterus and membranes a distance of six or seven inches and then, turning the catheter quickly, ruptured the membranes high up. Withdrawing the stylet I thus drew off through the catheter six quarts of liquor amnii, and the uterus contracted down to about two inches above the umbilicus. There was no shock, but a feeling of great relief: the pulse fell to 88. There were active fœtal movements. I then withdrew the catheter, pinned a binder firmly around the body from the breasts to the fundus uteri, and waited. In three quarters of an hour uterine contractions set in and continued feebly during the night: the patient was comfortable, however, and slept between the pains: there was a constant, slight dribbling of the amniotic fluid. During the following day there was a cessation of pains, and the patient was comfortable, taking a proper amount of nourishment and sleep: there was, however, retention of urine which necessitated the use of the catheter.

At 2 o'clock A. M., March 23d, pains began again with somewhat increased vigor, and at 6.15 A. M. the os was dilated and expulsive pains began. A fœtus presenting the head, O. R. P., quickly descended into the pelvis, the occiput rotated forward, and the child was born still in fifty minutes from the beginning of the stage. A second fœtus now appeared at the brim presenting O. R. A.; but in the temporary cessation of pains the head disappeared, and a shoulder entered the pelvis. I did not rectify the malposition, but waited to see what would happen. Strong pains very soon began, and in thirty minutes from the birth of the first fœtus the second was born by spontaneous evolution, *corpore conduplicato*. The single placenta was expressed ten minutes after and was followed by a very moderate hæmorrhage, which however was promptly controlled by ergot. The patient suffered no discomfort during the puerperium except from the breasts, which were hard and tender during three days, but which subsided without treatment. On the second day the temperature reached 101.2° F., but declined the following day and was not above normal after the fourth day. Carbolized vaginal douches were used for the sake of cleanliness, and small doses of ergot and opium were employed to promote involution of the uterus. On the tenth day I measured the abdomen and found the circumference at the level of the umbil-

[1] Read before the Obstetrical Society of Boston, February 9, 1884.

icus to be 27.5 inches, and the distance from ensiform cartilage to pubes 12 inches: there had been an increase, therefore, from the dropsical distention, of 11.5 inches in the girth and of 6 inches in the distance from the xiphoid cartilage to the pubes, in a woman much below the medium size.

The chief dangers to be apprehended in cases of this nature are

1. Shock, from the sudden discharge of a large amount of fluid and consequent disturbance of the circulation;

2. Hæmorrhage, from the inefficient post partum contraction of a uterus whose muscular tonicity has been much impaired by undue distention.

To avert the danger of shock the membranes were ruptured high up in the manner described; and as, fortunately, the fluid did not escape around the catheter but only through it, I was able with my finger on the end of the catheter to control the escape of the fluid while the pulse was carefully watched. To avoid the danger of hæmorrhage I purposely withdrew only a portion of the superfluous fluid and left the remainder to trickle away slowly: this gave time for the patient to have needed food and rest, and for the uterus to regain in a measure its muscular tone before it should be called upon to expel its contents. The uterus was also carefully supported post partum, and with the use of ergot firm contraction was maintained.

In accordance with the rule in twins from one ovum the fœtuses were of the same sex; namely, both were boys[1]: they weighed one pound and one pound two ounces respectively. One fœtus was club-footed, the other bore no outward mark of abnormality. The placenta was single and weighed one pound one ounce: macroscopically it was of normal appearance. There was one chorion, and there had doubtless been originally two amnions; but the septum had partly atrophied, and as usual in such cases the remaining septum was of falciform shape. A specimen of the amniotic fluid was submitted to Dr. Charles Harrington for chemical analysis; he reported, however, that it contained nothing abnormal. The placenta, membranes and fœtuses were sent to the pathological laboratory of the Harvard Medical School for examination: most unfortunately the fœtuses were lost, and with them the possible opportunity of throwing light on the pathology of this obscure subject. Dr. W. F. Whitney very kindly examined microscopically the placenta and membranes; but there were no pathological appearances.

The pathology of hydramnios has long engaged the attention of obstetricians and has been the subject of much critical and polemic writing. Prof. Charpentier, in a long and exhaustive treatise,[2] concludes that the pathological anatomy of this affection is far from presenting the least certainty; for, he says, it is not rare to find the lesions to which hydramnios has been thought to be due in cases where there had been no trace of hydramnios. But before attempting to seek the cause of the increased quantity of amniotic fluid constituting the condition known as hydramnios, let us consider for a moment the probable origin of the fluid existing under normal circumstances. This subject is still a matter of controversy; but the opinions of those commanding the greatest weight of authority warrant the present belief that the fluid is a fœtal product and that its sources are

1. The capillaries of the skin.

2. The capillary network described by Jungbluth and known as the vasa propria of the chorionic boundary-membrane of the placenta, lying just beneath the amnion, and anastomosing with the umbilical vessels.

3. The kidneys.

In accordance with this belief, the sources of an abnormal increase of the liquor amnii are to be sought in the fœtus and in the placental circulation: in an excessive kidney- and skin-secretion of the fœtus; and in abnormal transudation from the vasa propria of the chorionic boundary-membrane above mentioned, which may remain patent beyond the time when their gradual obliteration normally begins, namely, after the first half of pregnancy. In short the cause is to be sought in mechanical disturbances of the fœtal circulation, especially of the circulation of the umbilical vessels with which the vasa propria anastomose.[3]

A maternal influence in the production of the superfluous amniotic fluid is not, perhaps, to be completely excluded. Spiegelberg pointed out that from the numerous vessels of the decidua vera, after the union of this membrane with the decidua reflexa, a transudation might well take place into the amniotic cavity. Carl Braun does not accept this view, but believes that such transudations collect either between the uterus and the chorion and give rise to the so-called hydrorrhœa gravidarum, or, very rarely, between the amnion and the chorion simulating but not constituting a true hydramnios.[4] Braun therefore attributes the origin of the superfluous fluid solely to the mechanical disturbances of circulation above alluded to.[5]

Some recent observations of Otto Küstner of Jena form an interesting and suggestive contribution to the literature of this subject, even if they do not afford any positive knowledge. In 1876 Küstner published[6] an account of the autopsy in a case of twins associated with a high degree of amniotic dropsy, and deduced from the post mortem appearances the probable origin of the superfluous fluid. The smaller fœtus bore only the signs of death from suffocation: the larger, however, revealed

a. Hypertrophy of the heart, of both ventricles equally;

b. Cirrhosis of the liver, which was also smaller than normal;

c. Ascites to 150 ccm. (℥v circa).

The examination was incomplete from the fact that the placenta and membranes were not seen by Küstner: in fact it was not known whether or not the diseased fœtus had lain in the hydramniotic sac; but from such facts as he had Küstner explained the occurrence of hydramnios as follows:—

The cirrhosis of the liver, which was probably the primary factor, resulted in compression of the branches of the hepatic veins and of the portal vein. As the umbilical vein opens by one of its branches into the portal vein (the other branch constituting the ductus venosus), the portal vein may be said to have two separate places of ramification; namely, an intra-fœtal, in

[1] It is an interesting fact, worthy of notice here, that in the great majority of cases of hydramnios the fœtuses are female. In McClintock's thirty-three cases there were only eight boys, and of Spiegelberg's cases the fœtuses were female almost without exception.

the abdomen of the fœtus, and an extra-fœtal, in the placenta. Compression of the portal vein in the liver would cause increased blood tension in both the intra-fœtal and extra-fœtal distribution of this vein. This increased tension could be compensated for by an increased heart action: if the tension increase slowly, the heart hypertrophies gradually and accommodates itself to the increased demand upon it. But when finally the hypertrophy no longer suffices to compensate for the increased venous tension, transudations naturally result. These transudations take place from the intra-fœtal distribution as ascites; from the extra-fœtal, as hydramnios.

In 1880 Küstner had a case of acute hydramnios which presented striking analogies to the case above mentioned, and he has published[1] the case in full with a synopsis of several cases observed by others. In this second case premature labor with twins took place in the sixth month. The fœtuses were both female and lay in separate amniotic sacs: the first sac, in which lay the larger fœtus, contained by estimate thirty pounds of fluid; the second, which did not rupture until after the birth of the first fœtus, contained but little fluid. The second fœtus presented no abnormality: the first and larger fœtus, which lay in the dropsical amnion, showed the following post-mortem appearances: —

Great enlargement of the liver (apparent by abdominal palpation), its vessels uniformly enlarged, the perivascular spaces enlarged and partly filled with blood corpuscles, the connective tissue around the vessels not increased. Ascites to the amount of 30 to 40 ccm. Effusion in both pleural cavities. Hypertrophy of both ventricles of the heart. A number of circumscribed enlargements of both umbilical arteries, the umbilical vein presenting no changes. The single placenta weighed 410 grams (14.5 ounces), and its cotyledons were soft and œdematous. The cord belonging in the dropsical amnion had a central insertion and was œdematous; the other cord had a velamental insertion and was slender: both placenta and membranes were fattily degenerated to a great degree. The fluid from the dropsical membrane, in addition to the usual constituents, contained 0.07 per cent. of urea, which is more than double that which Fehling considers the normal amount.

Comparison of Küstner's two cases reveals certain striking similarities. In both cases the fœtuses were of like sex, but of different degrees of development; in both, the smaller fœtus was healthy, while the larger showed marked pathological changes affecting chiefly the liver and heart. In both cases the heart was hypertrophic, in the earlier case corresponding in size to that of a child four months old. In both cases there was ascites. The changes in the liver, however, were different: in the earlier case there was well-marked cirrhosis, and the liver was small, pale, and anæmic; in the later case the liver was enlarged and presented the appearances above stated. Küstner considered, however, that both livers were examples of the same process — interstitial hepatitis — the former case being in the last stage, and the latter case in the first. From the high per cent. of urea in the liquor amnii of the second case Küstner concludes that an abnormally large amount of urine was voided by the fœtus, owing to the increased action of the hypertrophied heart.

In addition to his own cases Küstner has collected four others of well-marked dropsy of one amnion in twins from one ovum; that is, where the placenta is single, with one chorion and two amnions. In all these cases the heart was hypertrophied and in one case dilated. In three of the cases the liver was small and cirrhotic; in two, in what Küstner considered the hypertrophic stage of interstitial hepatitis; in the remaining case the condition of the liver was not noted.

These cases, while too few in number to prove anything, yet serve to illustrate in what way disturbances of the fœtal circulation, whether originating in the heart or in the liver, may lead to a dropsy of the amnion. The one condition necessary, it seems to me, to a serous transudation is a venous stasis: whether the prime disturbance is in the heart, in the liver or elsewhere, it matters not, provided the blood tension becomes so great as to cause capillary transudations. It seems to me not irrational to suppose that excessive convolution of a long fœtal cord might so retard the blood stream with undue friction as to lead to circulatory disturbances. Again, an active congestion of the fœtal kidneys, with coincidently increased arterial tension produced by a hypertrophied heart, would lead to an increased urinary secretion which, evacuated into the amnion, would increase unduly the amount of the liquor amnii: such seems to have been a factor in Küstner's second case.

In cases of twins from one ovum the placental vascular distribution is such that a considerable number of cotyledons are common to the circulation of both fœtuses, and it is possible that one fœtus may thereby gradually appropriate an undue portion of his fellow's blood: this would explain why in one-ovum twins one is usually larger than the other. It may be, too, that consequent upon the increased proportion of blood circulatory disturbances may ensue in the larger fœtus, to compensate for which the heart may hypertrophy and thus lead the way to serous transudation. Certain it is that hydramnios occurs frequently in connection with twin pregnancy; but while in some cases of record the larger fœtus has been found to occupy the hydramniotic sac, the cases are too few to warrant the assertion that it is always so.

It will be seen, therefore, that the pathology of this affection is still involved in uncertainty; but recent observations have done much to illuminate the subject, and in due time doubtless the causes of hydramnios will be as clearly demonstrated as those of other pathological conditions at one time equally obscure.

A CASE OF MONOMANIA.[2]

BY W. A. GORTON, M. D.,
Assistant Physician Danvers Lunatic Hospital.

So much has been included under the term monomania, and it has been to such an extent made synonymous with other and varying terms, that it is little wonder that the propriety of its existence as a separate form of insanity should have been disputed. Still, among the great insane multitude coming before us for review or treatment, every now and then a case occurs which seems in certain fairly well-defined respects to be entitled to consideration as a lunatic in a far different sense from the victim of acute or chronic mania or melancholia. Among the Germans such a distinc-

[2] Read before the Boston Medico-Psychological Society, March 6, 1884.

tion has long existed, and the French, since the time of Esquirol and Pinel, have described cases to which they have applied the term monomanie. By British writers, the propriety of the term has been questioned, but most of them have been forced to employ it in their descriptions of certain cases, either with or without some degree of modification. The present case may serve to illustrate the type of disease to which the term is most commonly applied.

C. V., aged forty-six, married, is the son of a musician and school-teacher, and was born in Germany. So far as can be learned the father was a man of respectable ability, largely self-educated, and all his life dependent upon his earnings for his support. In Germany he held the position of government school-teacher, but relinquished it to come to this country when the patient was seven years of age. He (the father) is said to have been somewhat eccentric. He died at the age of seventy-four, from some acute cerebral disorder. The mother was of average ability and without any known mental peculiarity. Patient has one brother and one sister, both of whom are a little peculiar, being of an emotional and excitable temperament, but neither betray any actual insanity. The brother is quite an accomplished musician, and beside playing in the orchestra of a leading theatre holds a position of trust in a prominent dry goods house of a large city. He is very fond of discussing his brother's case from a quasi-scientific stand-point. On one occasion he brought to me a sackful of popular works upon mental philosophy from which he proposed to read a description of the patient's case, and to point out the proper treatment to be pursued. Later he had an interview with the patient, and in attempting to read the same description to him so enraged him that a fight between them for a time seemed imminent. The sister is devoted to the patient, thinks he is not insane, and tries whenever she visits the asylum to convince the officers that he ought to be liberated. Beyond this persistence and a somewhat emotional manner her conduct exhibits nothing demanding special comment.

As a child the patient was somewhat delicate, but appears to have had no special disease, certainly nothing resembling any cerebral affection. He manifested a good degree of intelligence, learned readily, and early displayed a taste for music and drawing, in both of which he received careful training by his father, becoming a good performer upon the violoncello and a fairly good architectural draughtsman. He was temperate in his habits, and not addicted to sexual excesses of any kind so far as can be learned. His sister declares that as a young man he had a most gentle and affectionate disposition, but displayed great sensitiveness to opposition or criticism, and cherished a fanciful sense of honor which led him to explosions of temper whenever anything he considered unfair treatment of himself or others came to his knowledge, or whenever anything which he thought vulgar or indelicate was done in his presence. His education having been wholly undertaken by his father he lived almost wholly at home, where he had no trouble, until he was twenty years of age. From this time, or when he began to support himself, his mental peculiarities began to be more prominent, and he began to display an intolerance of discipline and restraint that brought him into constant collision with his employers. Failure to obtain as much pay for his work as he demanded led him to think his employers unjust, and finally to believe that all who tried to support themselves were prevented from succeeding as they ought by the tyranny and meanness of the people employing them.

For the past ten years his frequent quarrels with his employers, and his refusal often to work for men who offered any criticism of his performance, have prevented his being steadily occupied either as a musician or draughtsman, and he has tried various other occupations to eke out his earnings. He has been an unsuccessful canvassing agent for a book publisher, getting one subscriber who refused to pay for the book when delivered; tried canvassing for a newspaper without getting any subscribers at all; tried collecting bills for a physician on a commission of ten per cent., collecting twenty dollars the first day, and not a cent for the next three weeks. These quarrels and failures never induced him to yield any of his self-constituted rights in an effort to live without friction and discomfort, but rather strengthened his belief that the world was going wrong.

He seems to have manifested no definite delusion until 1877, when he was arrested upon a groundless charge of felonious assault and locked up for a night in the police station. The fact of his arrest and of the charge made against him was published in the daily papers and never retracted, although no case was made against him. From that time he has regarded the police as a vile body of men, encouraged and paid by the rich to browbeat the poor, and especially himself. On a later occasion he became involved in a quarrel with the proprietor of a theatre in the orchestra of which he was playing, which resulted in his forcible ejection from the building, during which process his instrument was broken. He at once wrote to the chief of police asking for the arrest of the manager for assault and battery, and urging that he be sued for breaking his instrument. The police paying no attention to his letter, he wrote them a postal card accusing them of venality and of hostility to him. At various other times the police have requested him to move when he has been standing upon the street, and in every instance he has regarded their action as a personal insult and an inexcusable outrage. In consequence of these acts of the police he wrote certain postal cards to various newspaper editors, expressing his opinion, as he termed it, and protesting against the system of injustice to which he believed himself subjected. He had also from time to time written letters upon the labor question, which he declares were temperate arguments upon the subject and intended only to draw attention to the deplorable condition of the working classes.

He appears to have kept himself within legal limits until 1882, when he began a wholesale writing of abusive and threatening letters to various people of prominence. Complaint having been made he was arrested in June, 1882, declared insane, and committed to the Taunton Lunatic Hospital. When arrested he was in his own house, and made a stubborn resistance, shooting at the officer who arrested him. He explained the shooting by saying that he did it in self-defense, believing the police to be about to kill him. He remained at Taunton until August, 1882, when upon his written promise to abstain from writing letters, and to conduct himself properly in other respects, he was released.

Upon assuming the care of himself and family he seems to have found the strain too great for his self

control, and he very soon began again to send abusive postals, though he says he was careful to avoid any vulgarity of expression this time, as he thought he would thus escape arrest. Finally, he became so great a nuisance that he was arrested and committed, August 23, 1883, to the Danvers Lunatic Hospital upon the following medical certificate: —

"For many years he has been peculiar, and at times has threatened violence. He was committed to the Taunton Hospital June 22, 1882. He has been writing many abusive postals to respectable gentlemen, and was arrested by order of the Police Commissioners. Sent to the Boston Lunatic Hospital as an emergency case August 20th." "He is excitable and very suspicious. He believes that the world is all wrong, that there is no chance for the poor, that he is the victim of persecution, and has many enemies, that every one who differs from him is a liar and a villain. He can see no impropriety in the postals he has written, and considers all proceedings against him an outrage. His word and written promise have proved entirely unreliable. All these things have rendered him an annoyance to many whom he thinks have injured him. In our opinion he is liable to be violent at any time, and is a dangerous man, who probably never will recover or be safe to be at liberty."

The notes of the examination made upon admission are as follows: He is of medium height, of rather slender build, is somewhat pale, and appears to be imperfectly nourished. He has a well-developed, symmetrical head, and clear-cut and intelligent features. Hair light brown, partly gray; blue, rather prominent eyes; pupils equal in size, and readily responsive to light and darkness. Facial muscles active, and betray slight tremor while he is speaking. Tongue is protruded without difficulty, is straight, and shows a moderate degree of fibrillary tremor. There is no apparent abnormality of the thoracic organs, except that the heart sounds are somewhat ill-defined and the cardiac action irregular. Pulse is 80. Has inguinal hernia of the left side, which is supported by a truss. Hernia has existed for several years, developed slowly, and is not due to traumatism. Genital organs apparently normal.

There is considerable tremor of the limbs during voluntary movements, but no more than is often seen in persons of a sensitive organization undergoing examination for the first time. No local paralysis of motion or sensation can be found. The patellar reflex is markedly exaggerated.

He is quiet and gentlemanly in manner, but seems to be laboring under excitement, which he subdues only with great effort, as he fidgets uneasily when questioned, and is querulous and abrupt in certain of his replies. He is disposed to be noncommittal, but admits that he has been writing postals which have brought him into trouble. Says he sees no impropriety in them, as they were mostly written to people whom he did not know, even by sight, and whom he had no intention to injure.

Admits that those written last year were abusive and vulgar, but insists that he was careful this year to avoid any indecent expressions. Says he did not expect any personal benefit from writing, but thought he might as well express his opinion to people disposed to neglect or trample upon the rights of the poor. Thinks society is imperfectly organized, because people who have money keep it all to themselves, and do not give the laboring classes any chance to get ahead. Believes the rich ought to furnish proper employment at proper wages to the poor. Does not understand that all have the same right to get money, and insists that poverty and hardship come only from the cruelty of the rich. Asked if he expects to revolutionize the existing state of affairs, he says, "No, I only wanted to express my opinion." Said the police and rich people were all against him, and, intimating that the examiner was also one of his enemies, he declined to talk further. Speaks with a slight foreign accent, but with unimpaired articulation. Within a week after admission a paroxysm of excitement occurred. He had asked for his discharge, and had been told that as he had been duly committed to the hospital as an insane person it would be necessary for him to remain long enough under observation to satisfy the superintendent that he was not insane before he would feel justified in discharging him. At this he became furious, began to gesticulate wildly, assumed an intensely dramatic attitude and expression, and shouted, "You have no right to say I am insane; you know I am not insane; in the name of God I say I am not insane. In the name of God, I say my liberty has been unjustly taken from me; in the name of God, I say you are a liar if you pronounce me insane; in the name of God, I demand justice and liberty." In this way he talked, or shouted rather, for several minutes, pacing excitedly about his room, and presenting the insane manner in a degree not to be described in words. Half an hour later he was quiet, and rational, but justified his previous conduct by saying that no man had ever been as unjustly treated as himself, and that it was the only way in which he could adequately call attention to his wrongs. For several weeks he refused to go out of doors, but when two or three strong attendants came to take him out he went without resistance, protesting, however, that it was an outrage and an injustice to make him submit to the farce of going out for a walk while he was in reality a prisoner in a lunatic asylum. About a month after admission he made a bungling effort to escape by removing his window. Since he has been in the hospital he has had frequent outbreaks, almost exactly like the one described. They are always of short duration, and although at times his manner has been threatening in the extreme, he has not attempted any actual violence. He prefers to be alone as much as possible, passing much of his time in his own room reading papers furnished by his relatives. He has refused books that have been given him, regarding the offer as an insult, and declaring that he would not read them while deprived of his liberty. He refuses to do any work or to engage in any game or amusement, declaring that he has no taste for such things while held as a prisoner. He has been repeatedly requested to join the hospital orchestra, but he always becomes angry, and declares that is a "put-up job," as he calls it, to get music for nothing. Drawing materials have been offered him, but he always has refused to use them, saying, "I shall get nothing for my work, and I can never be interested or amused while deprived of my liberty." He regards the hospital officers as his enemies because they do not liberate him, and declares, "in the name of God," that no earthly consideration would induce him, were he in their position, to detain a sane man like himself for a single hour. He becomes very cautious in manner when questioned about himself, saying, "I prefer to say as little as possible

about my past life, for my position is a peculiar one. I am shut up here as a lunatic by my enemies, and I must be careful about what I say, as you are one of those who are against me, and will make use of my statements to injure me." Upon general topics he converses with ease and considerable ability. His perception is good, his memory accurate and retentive, and his conclusions are generally just and fair. Except for his total inability to see the impropriety and absurdity of his past conduct his intellect seems to be very little impaired. He admits that he was foolish to write so many letters, but only because of the bad result. He is still an assiduous letter writer, but writes only to his wife and sister, begging them to come and release him. Frequently writes two or three letters in the same day, and all are worded almost exactly alike. They present a characteristic appearance, nearly every other word being heavily underscored, and the phrase " in the name of God " is often repeated.

He denies that he is in any sense inspired, and denies that he has ever experienced any hallucinations of sight or hearing. He reasons very clearly upon the subject of hallucinations and inspiration, and conclusively shows that his delusions spring from his actual experiences. Says, " I am not inspired. I have never had in a dream or in any way any inspiration or ever heard any voice urging me to do what I have done. I only felt that because of these acts of injustice done me by the police and others I had a perfect right to express my opinion in the way I did, and what I said was my own opinion, and was not an inspiration in any way whatever." He does not entertain expansive delusions as to his social or professional capabilities, but declares that he is a good musician and an average draughtsman, and that if given steady employment and justly treated and paid he would be perfectly satisfied, and would trouble no man. Since he came to the hospital he has had a fair appetite, has preserved a good degree of nutrition, and has slept very well. He has made no complaint of bodily indisposition, and has taken no medicine.

This case is interesting chiefly on account of its clearly defined character and its medico-legal possibilities. The intellectual deterioration is so slight and the patient's capacity to explain his delusions is so great, and so similar are many of these delusions to the views of Dennis Kearney, Herr Most, Henry George, and other socialist agitators, that he might very easily seem no more insane to a miscellaneous body of the laity, such as compose the ordinary jury, than would the men just mentioned. To be sure they have only spoken to masses of men about other masses of men, and they have not so far lost self-control as to precipitate quarrels with individuals in attempting personal applications of their own avowed principles, but their language, notably that of Kearney, has been as violent and outrageous as the worst fulminations of this patient at his most excited moments. The loss of self-control, one of the strongest evidences of insanity in this case, while all powerful in determining the opinion of the medical expert, is much too delicate a question for decision by a jury, and would very likely be overlooked in the present case were the patient allowed to testify in his own behalf.

The question of responsibility for grave crimes might in this case be a delicate one to settle. Certainly with the present legal definition or with Hammond's definition of criminal responsibility it would be difficult to say that this man does not come within the limits of responsibility understanding, as he does, the difference between right and wrong in the ordinary ethical sense.

Briefly summarized the history shows that this man probably inherited an unstable mental organization, that his early life was passed under very bad auspices, his education, conducted solely by his father, a man of peculiar and eccentric habits, doubtless serving to intensify rather than to restrain any morbid mental peculiarities shown in youth, and his seclusion from that society in which he was to live having, to a certain extent, unfitted him for living in it. The cultivation of his artistic instincts at the expense of a careful training in the practical affairs of life placed him in a position to compete at a disadvantage with others in the struggle for existence, and the dissipation of his energies in undertaking two professions further increased this disadvantage. His failure to succeed as well as he had hoped forced him into a morbid state of mind, out of which, under the exciting influence of an unfortunate chain of circumstances, vague ideas of ill treatment emerged as systematized delusions of persecution. As these delusions became sharply defined they so far dominated his mental processes as to destroy his self-control and lead him to the perpetration of acts of lawlessness which may be taken as forerunners of more serious manifestations, as the history of similar cases, almost without exception, has been one of progressive mental failure. Should hallucinations develop it seems highly probable that this patient, with his present mental attitude, might, under their influence, be goaded to the commission of the worst possible crimes.

The case closely resembles the description of Primäre Verrücktheit given in the *Psychiatrisches Centralblatt* for December, 1877,[1] but differs from it notably in the absence of hallucinations of the special senses, of anything approaching a belief in divine inspiration, and in its freedom from expansive delusions of a social or political character. It has been described as a case of simple monomania, as it seems to fall very clearly within the limits of Spitzka's definition of that disease, namely, "a chronic form of insanity based on an inherited or acquired neuro-degenerative taint, and manifesting itself in anomalies of the conceptional sphere, which, while they do not destructively involve the entire mental mechanism, dominate it."

A CASE OF PLACENTA PRÆVIA, MOTHER AND CHILD LIVING.[2]

BY EDWARD JACOB FORSTER, M. D.

THE case which I present to-night seems of sufficient interest to report in full, as the method employed to terminate the pregnancy, manual dilatation of the os, is one which is not as yet recognized by the text-books, although well known to members of this Society, as it was first suggested by one of our number, Dr. A. D. Sinclair, who prior to 1865 successfully delivered a case of placenta prævia in this way. Since then he has reported nearly a dozen cases treated in the same manner and with the same result. Dr. Richardson, in an article in vol. 5 of the Gynecological Transactions, has strongly advocated this method of inducing labor when

[1] Journal Mental Science for April, 1879.

[2] Read before the Obstetrical Society of Boston, February 9, 1884.

from any cause it may be necessary during the later months of pregnancy. In this vicinity, at least, it is, I believe, the recognized practice superseding entirely the tedious methods formerly employed, as electricity, the hot and cold douche, the introduction of foreign bodies with the view of separating the membranes, or the dilators of Barnes.

When the placenta is situated over the os there can be no absolute safety for the mother until delivery is accomplished: a hæmorrhage of such an extent as to rapidly prove fatal may take place at any moment, when once the placenta from any cause becomes separated from its insertion. In such cases as this this method seems particularly applicable; for while we have the means of rapidly terminating the pregnancy, the presence of the hand in the os can to a great extent control the flooding.

On the 8th of January, 1883, I was called to Mrs. R., forty-eight years old, born in Ireland, of previous good health. She had had ten living children without more than the usual amount of trouble, and one miscarriage eighteen or nineteen years ago. Her last child was born in November, 1875. While carrying her sixth child she menstruated throughout her pregnancy. This was probably a partial placenta prævia. At my visit late in the afternoon I found her in bed, and she gave me the following history of the present pregnancy: Motion was first noticed about 6th August, 1882. Her general health had been good with the exception of heart burn, for which she had taken magnesia and other remedies without relief. Her bowels were regular. About five P. M. Thursday, 28th December, without having any pains she passed a few clots: again on Sunday, the 31st, there was slight flowing without pain. From then one week passed and she soiled only two cloths until the midnight before my visit, when she was awakened from sleep and found blood in the bed: the flowing lasted about half an hour, then slight pain in twenty minutes and more blood, little if any after and no pain except such as was caused by the motion of the child. Examination per vaginam settled the diagnosis.

Believing, as I have before stated, that while pregnancy lasted there was no safety for the mother, and that the serious character of the case needed prompt interference and careful management, I asked and obtained the services of Dr. W. L. Richardson in consultation. It was decided at once to proceed to induce labor. After stating to the patient the chances of leaving the case to nature consent was readily obtained. The patient was etherized, manual dilatation performed, and at a quarter of two A. M. a living male child was delivered by version, the operation not lasting over three quarters of an hour. There was comparatively but slight loss of blood. Dr. Richardson, who performed the version, found some difficulty in bringing down the foot and unavoidably fractured the femur: as he is present, the explanation of this accident I leave to him.

Dr. Richardson had gone home, Dr. Blood who had taken charge of the anæsthesia was preparing to do the same, when the nurse hastily summoned us again to the bedside, where we found the patient in a state of collapse. The uterus was quickly seized and little hæmorrhage ensued: brandy, quinine, and laudanum were freely used and the circulation was soon restored. While these remedies were given by the mouth three subcutaneous injections in the thigh were given, a drachm each of brandy and fl. ext. of ergot, and a drachm of a solution of quinine containing five grains. The condition of collapse lasted long enough for the husband to become thoroughly alarmed and again summon Dr. Richardson. "January 16th the sore spot on the left leg made by injecting brandy discharged pus freely. January 17th. Quinine-sore discharged but little." I regret to say that the foregoing notes by the nurse are the only ones which I have of the appearance of the ulcers caused by the subcutaneous injections, having lost those which I had carefully prepared as well as some sketches. Suffice it to say, each left a deep circular ulcer about an inch in width and more than that in depth, which were several weeks in healing: this, as regards ergot, is contrary to the teaching of Mundé, who says in his Minor Surgical Gynecology he never knew any trouble to follow its use. At the point where the injection of quinine was given an eschar was formed which remained quiescent for about three weeks, when falling off disclosed one of the ulcers above mentioned. The quinine used was the sulphate. Edes recommends the use of hydrobromate or hydrochlorate for hypodermic injection as being less irritating: this we did not then know, or we might have had one less ulcer to annoy the patient.

An interesting point is the shock or collapse which followed the delivery and which perhaps might have been avoided if the rule, which I remember Dr. Gordon Buck of New York advocated some years ago in the *Boston Medical and Surgical Journal*, of giving an alcoholic stimulant always before etherization had been followed. It has been suggested to me that the condition of the patient which alarmed us was not shock, but was possibly due to the entrance of air into the circulation.

I am happy to record the ultimate recovery of the mother. Last week I heard the child was running about.

RECENT PROGRESS IN SURGERY.

BY A. T. CABOT, M. D.

LAPAROTOMY IN OBSTRUCTION OF THE INTESTINE.

Schramm[1] reports three cases of laparotomy performed by Miculicz, and has collected 190 cases in which this operation was done for occlusion of the intestine; 64.2 per cent. of these cases were fatal, but investigation shows that the rate of mortality during the last ten years has been 58 per cent., having been 73 per cent. previous to that time. This shows an improvement of 15 per cent. in consequence of better technique and antiseptic precautions.

From a study of these cases Schramm draws the following conclusions: —

As the tendency is to death from collapse it is manifestly wise to operate early, before the patient is weakened, and before peritonitis has developed. This is especially true in cases of invagination in children, when a favorable result can only be expected if the operation is done within the first forty-eight hours, as after this time the intestinal surfaces are almost hopelessly glued together. In adults, on the other hand, if the symptoms of strangulation are not severe it is well to wait until there is evidence of failure of strength.

The incision is best made in the median line, especially when the seat of the obstruction is not known.

[1] Arch. f. klin. Chir., Band xxx., Heft 4.

If an intussusception is difficult to pull apart, the lower end of the inclosed portion may be kneaded and pressed back with one hand while with the other the entering portion of intestine is gently drawn out. In a difficult case the invaginated portion may be firmly compressed to reduce its size (as recommended by Hutchinson) before any traction is applied.

In extensive irreducible invaginations of the large intestine, and when gangrene has already commenced, it is advisable to open the bowel above the obstruction, to establish an artificial anus, and then to wait for the spontaneous separation of the gangrenous part.

In case of a short irreducible intussusception of the large intestine, or of an irreducible invagination of the small intestine, Schramm would advise resection of the affected portion with union of the ends by suture. This latter treatment would naturally be proper in case of carcinoma.

When the source of obstruction cannot be discovered by investigation of the localities where the trouble is most commonly situated, the search should be conducted in the following manner: A presenting coil of intestine should be seized by the assistant and held fast in the wound while the operator, starting from this point, draws the intestine out bit by bit, always proceeding along the gut in the same direction and returning the coil last examined as the next one is drawn out. If from the appearance of the intestine (redness and amount of distention) it becomes manifest that he is receding from the point of obstruction, he should return to the original coil which the assistant still holds and start from it in the opposite direction. If a band is reached, behind which the intestine is strangulated it should be tied close to its insertions and cut away completely.

In case a twist or knot is found which cannot be unloosed, several methods have been adopted to re-establish the patency of the canal. Reali cut the intestine in two and reunited the ends after disentangling the knot. This patient recovered. Also a union may be effected between the intestine above and below the knot after the manner described by Wölfler in his operation of gastro-enterotomy. If the twist is already gangrenous it may be cut out and the ends either joined together or brought out through the wound.

In regard to the operation of enterotomy for obstruction, without an attempt to find the cause of the obstruction, a procedure strongly recommended by Maisonneuve, Schramm points out the danger of making the opening too high in the intestinal tract or of opening a coil below the obstruction, and urges further against it that the patient is left to the danger of gangrene of the strangulated intestine.

In the *American Journal of the Medical Sciences* for July, 1884, Dr. R. H. Fitz publishes a paper upon Persistent Omphalo-Mesenteric Remains, in which he calls attention to the important part that the diverticula and fibrous cords formed by a persistence of the omphalo-mesenteric duct or vessels may play in causing intestinal strangulation and obstruction. He draws the following conclusions of practical surgical importance: —

"(1.) Bands and cords as a cause of acute intestinal obstruction are second in importance to intussusception alone.

"(2.) Their seat, structure, and relation are such as frequently admit their origin from obliterated or patent omphalo mesenteric vessels, either alone or in connection with Meckel's diverticulum, and oppose their origin from peritonitis.

"(3.) Recorded cases of intestinal strangulation from Meckel's diverticulum, in most instances at least, belong in the above series.

"(4.) In the region where these congenital causes are most frequently met with an occasional cause of intestinal strangulation, namely, the vermiform appendage, is also found.

"(5.) It would seem, therefore, that in the operation of abdominal section for the relief of acute intestinal obstruction not due to intussusception, and in the absence of local symptoms calling for the preferable exploration of other parts of the abdominal cavity, the lower right quadrant should be selected as the seat of the incision. The vicinity of the navel and the lower three feet of the ileum should then receive the earliest attention. If a band is discovered, it is most likely to be a persistent vitelline duct, that is, Meckel's diverticulum, or an omphalo-mesenteric vessel either patent or obliterated, or both these structures in continuity. The section of the band may thus necessitate opening the intestinal canal or a blood-vessel of large size. Each of these alternatives is to be guarded against, and the removal of the entire band is to be sought for, lest subsequent adherence prove a fresh source of strangulation."

In connection with Dr. Fitz's article the following case of intestinal obstruction recently reported by Mr. Clutton[1] to the Clinical Society of London is of interest: —

The patient, a boy of ten, had had several previous attacks of obstipation, none of which had been of more than two or three days duration, and which had always been relieved by enemata. The attack in question, accompanied by continued vomiting, had lasted four days when Mr. Clutton was called by the attendant, Dr. Purvis. Laparotomy was decided upon.

When the abdomen was opened a collapsed coil of intestine was quickly found, and in bringing it to the surface a tight, ring-like cord could be felt and seen to be the cause of the strangulation. This band was seized by two pairs of forceps and divided, the ends being tied with catgut. The strangulation was now entirely relieved. The cord was found to have started from the top of a diverticulum two inches in length, and to have been attached by its other end to the wall of the same loop of intestine from which the diverticulum started, at a distance of about six inches. A portion of bowel, about three inches in length, between these two points of attachment was the part strangulated, and was of an extremely dark color, with a deep sulcus at each side. The boy made an uninterrupted recovery.

Mr. Clutton regarded this cord as the remains of the vitelline duct, which had remained patent for two inches from the ileum, and had formed a cord for some distance beyond. The free end of this cord he supposed to have become adherent to the intestine at the point where it was found attached. A portion of the gut between had slipped beneath the cord and become strangulated.

NEPHROTOMY BEFORE NEPHRECTOMY.

R. Clement Lucas[2] calls attention to the importance of incising and draining a suppurating kidney before

[1] British Medical Journal, May 17, 1884.
[2] British Medical Journal, March 22, 1884.

performing nephrectomy. He says: "It is not only that drainage relieves at once the patient, and in many instances is alone sufficient for cure, but that it renders a subsequent nephrectomy (when necessary) much less dangerous. Thus a double advantage is obtained. At first the patient is subjected to only a trivial operation, which is certain to give relief, and may effect a cure, and, secondly, should the course of events later indicate the advisability of removing the shrunken kidney, nephrectomy will have a greater chance of success. I showed in my paper [1] that six cases were all successful in which nephrectomy followed drainage, whereas nephrectomy for pyonephrosis with these cases abstracted has a mortality of fifty per cent. It is but reasonable to anticipate some such difference in the results, for, apart from the accidents which may happen in the attempt to remove a large and adherent bag of pus, it is evident that a much greater surface must be exposed to injury in removing a distended kidney than in excising a shrunken one. Further, drainage gives time and opportunity for the patient to gain strength before being submitted to the major operation."

PULMONARY SURGERY.

Krönlein [2] recently removed a nodule of recurrent sarcoma from the surface of the lung. After resecting a portion of the sixth rib, which was involved in the growth, it was found that the portion of the tumor that projected into the chest (about the size of a small fist) was adherent to the lung. This was easily separated with but little hæmorrhage. At this point in the operation the lung collapsed, and the dyspnœa was extreme, so that the administration of chloroform was discontinued. A nodule about the size of a walnut was now discovered in the periphery of the lung. It was drawn up to the opening in the chest wall and excised with the scissors. There was scarcely any bleeding, and what little did occur was checked by bringing the edges of the wound together with catgut sutures. The lung expanded with great rapidity, the wound healed readily, and recovery was complete at the end of three weeks.

The insignificant hæmorrhage from the lung tissue is the most interesting feature of this case.

In a recent editorial in the *Lancet* [3] the tapping of cavities near the apices of the lungs is regarded as a procedure of doubtful utility, but the opening of cavities near the base is thought to be justified in view of the great relief afforded by providing an easy outlet for the putrescent contents, which if they discharged through the bronchi would expose the patient to great risks of secondary lobular inflammation.

Krönlein, in the article quoted above, deprecates all attempts to clear out tuberculous cavities or to remove portions of diseased (tuberculous) lungs, and says that he should regard it as an advance in pulmonary surgery to go back to the advice of Richter, given in 1812, to operate only in case of an abscess carefully diagnosticated and accurately defined.

HYDROCELE. INJECTION OF IODINE.

Dr. Otto Weiss [4] has made some investigations as to the final results of the radical operation for hydrocele as at present practiced in Billroth's clinic. The cases were treated by the injection of a freshly-prepared mixture of equal parts of tincture of iodine and distilled water. From thirty-five to seventy grammes of this mixture were introduced in each case into the sac from which the fluid had been drawn. After this had been retained for five minutes, during which time the scrotum was gently kneaded, it was allowed to escape. Antiseptic precautions were observed throughout.

The pain following this operation was generally severe for from one half an hour to an hour. The patients were kept in bed for four or five days with the scrotum well supported.

Fifty-one cases have been thus operated upon in this clinic since 1876. Of these thirty-eight answered Weiss's circular of inquiry as to the final result, of which thirty-two reported themselves as entirely well, while in six the disease had recurred.

INJURIES OF THE THORACIC DUCT.

Boegehold [5] reports a case in which, during the removal of a malignant tumor of the neck, the thoracic duct was opened. Simple compression controlled the escape of chyle, and the wound did well.

Boegehold succeeded in showing by injection the existence in two cases of collateral trunks by which communication with the veins is maintained when the main duct is compressed or ligated.

CIRCUMRENAL TUMORS.

Sir Spencer Wells [6] reports a case in which he removed two large fibro-lipomatous tumors which lay encapsulated, one around each kidney. They shelled out quite easily for the most part, but the lower third of the left kidney adhered to the tumor surrounding it, and was torn off with it. The bleeding was controlled without great difficulty, and notwithstanding the injury to the kidney the patient, a lady of forty-eight, made a good recovery, and did not suffer from any disturbance of the urinary functions. The tumors weighed sixteen and a half and fourteen and a half pounds.

RETROGRADE DIVULSION OF THE ŒSOPHAGUS.

Professor Loreta,[7] of Bologna, who recently devised the operation of digital divulsion of the pylorus,[8] has within the past year introduced an operation which he calls "retrograde divulsion" for the treatment of a cicatricial stricture near the cardiac end of the œsophagus. A tight stricture in this region is almost always beyond the reach of successful treatment by the mouth.

Loreta's case was as follows: The patient, a man of twenty-four, reduced to an extreme degree by starvation, was operated upon October 24, 1883. Gastrostomy was first performed, and through the opening thus made a divulsor was passed into the stricture, and this was dilated to what seemed a sufficient extent. The wound healed by first intention with no sign of peritonitis. The patient could swallow easily the first day, and was entirely well at the end of a fortnight, although the future use of a bougie will probably be required to keep the passage patent.

— Morean de Tours, the celebrated French alienist, whose aphorism, "Le Genie est une névrose," made the groundwork of his great work on La Psychologie Morbide, is dead at the age of eighty.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M. D., SECRETARY.

FEBRUARY 9, 1884. The President, DR. C. ELLERY STEDMAN, in the chair.

DR. W. L. RICHARDSON exhibited a blank form which he had devised for recording cases of obstetrics in the out-patient department of the Boston Lying-In Hospital.

DR. G. H. BIXBY reported Five Cases of Abdominal Section. (Paper reserved.)

ACUTE HYDRAMNIOS.

DR. C. M. GREEN reported a case of acute hydramnios, with remarks on the pathology of this affection.[1]

DR. J. R. CHADWICK said that the most characteristic feature of this case was the extreme rapidity with which the abdomen enlarged, resembling nothing in his experience except ascites. The patient, though believing herself to be nearly four months pregnant in the middle of February, had observed no increase in girth; between that time and March 9th she had grown to the size of the end of the eighth month of pregnancy. The resemblance to ascites was enhanced by the very distinct wave of fluctuation which was felt throughout the greater part of the abdomen, and by the impossibility of defining by palpation the upper end of the uterus. Ascites was, however, excluded by his finding that the wave of fluctuation was not transmitted to and from the epigastric region, where the resonance was tympanitic, to the other parts of the abdomen, where it was flat. This point in the differential diagnosis between ascites and all encysted abdominal fluids (uterine, ovarian, vesical, etc.), is mentioned by Spencer Wells[2] in the following terms: "When fluid is free in the peritoneal cavity the wave of fluctuation may be felt not only where the sound is dull on percussion, but also beyond the line of dullness, even where resonance may be tympanitic. The intestines float in the fluid, and the fluid may be thrown in waves among them. But when fluid is contained within a cyst, fluctuation cannot be detected beyond the boundaries of the cyst. Hence the outline of the cyst, traceable by dullness on percussion, and the line where fluctuation can be perceived, must be the same."

Dr. Chadwick emphasized this diagnostic sign because it seemed to him to have been generally overlooked by even the most thorough and eminent writers, such as Thomas, Hart and Barbour, Goodell, Tait, and others. He had found it to be more reliable than any other sign.

An ovarian cyst complicating pregnancy was excluded by the sudden rapidity of growth, by the absence of a furrow in the abdomen indicating the line of demarcation of the cyst and the pregnant uterus, by the ubiquitous wave of fluctuation, and by the central position of the cervix uteri in the pelvis.

As to the source of the amniotic fluid, he could add nothing to its solution except to point out, in favor of its being contributed in part, at least, by the fœtal kidneys, that in those cases in which certain drugs administered to the mother have been detected in the amniotic fluid, they have likewise invariably been found in the first urine passed by the child.

[1] See page 121 of this number of the JOURNAL.
[2] Diseases of the Ovaries, page 130.

DR. RICHARDSON believed there would be less danger of entering the placental sinuses if the catheter, previously warmed, were passed without the stylet, and the latter subsequently introduced.

DR. CHADWICK said if the tip of the catheter, with the bent stylet contained, was kept away from the membranes, there would be no danger in his opinion, unless air was actually pumped in.

DR. DRAPER said that if the catheter entered a utero-placental sinus the negative pressure of the uterus would serve to draw in air.

DR. CHADWICK said that to illustrate more fully this unusual complication of pregnancy he would give briefly the notes of a case supplied him by Dr. Helen Morton, with whom he had seen the patient in consultation: —

Mrs. W., aged twenty-eight years, eight years married, had always been hysterical, and at times depressed mentally, but was otherwise in perfect health, as was her husband.

January 14, 1877, was born the first child. July 14, 1878, was born the second child at six and a half months of pregnancy; there was an excess of amniotic fluid; the child was weak, and had only superficial respiration; the umbilical cord continued to pulsate, and kept bleeding, although repeatedly ligated, until the death of the child, twelve hours after birth.

November 7, 1879, was born the third child, at the seventh month of pregnancy, with an excess of amniotic fluid; the cord pulsated and bled as before until death after four hours.

February 14, 1881, was born the fourth child, at the eighth month of pregnancy, there being marked hydramnios. The child was puny, jaundiced, had feeble respiration and pulsating cord for some time, but survived, and was nursed nine months.

In February, 1883, was born the fifth child, at the eighth month; the liquor amnii was so markedly increased that at the fourth month of pregnancy the uterus was as large as it usually is at six and a half months; the fœtal heart sounds were strong during the pregnancy. The cord beat for half an hour, when it was tied; the child died four hours later.

The patient conceived again on March 14, 1883, and Dr. Chadwick was called in consultation on June 9th, in the expectation that some means might be devised to prevent the recurrence of the hydramnios and premature delivery. He was unable to offer any suggestion, but subsequently advised the persistent use of chlorate of potash, which was done for a time, but he could not flatter himself that it had much if any effect. Early in the autumn she was seen by Dr. Fordyce Barker, who advised the use of viburnum prunifolium. There was no hydramnios in this pregnancy. At the seventh month nature made an effort for many days to expel the contents of the womb; but the uterine contractions were successfully arrested by the repeated administration by Dr. Morton of morphine. This, the sixth, child was born at full term, December 14, 1883. The child was small; the cord did not pulsate after ligation; the amount of amniotic fluid was normal. The patient was kept in bed from the middle of the pregnancy until delivery.

The above history shows a remarkable recurrence of hydramnios in successive pregnancies, even under the most favorable conditions of life and health.

DR. BIXBY alluded to the case of an anæmic woman whose abdomen was as large as at full term, but who did not think herself pregnant; he aspirated, and drew

off four ounces of amniotic fluid. Miscarriage ensued ten hours later.

The general consensus of the Society seemed to be that aspiration of the amniotic sac through the os, as suggested by Playfair, was sure to excite uterine contractions and terminate the pregnancy; and that the only available treatment was to induce labor when the distention became extreme. Anæmia should, of course, be appropriately treated when present, and various palliative measures could be resorted to.

DR. E. J. FORSTER reported

A CASE OF PLACENTA PRÆVIA, MOTHER AND CHILD LIVING.[1]

DR. CHADWICK had always used subcutaneous injections of ether in cases of collapse, and had found them equally efficient even if the patient were etherized. Dr. Sinclair and Dr. Richardson had also used ether for this purpose.

DR. RICHARDSON said he was frequently astonished at the way physicians temporize and delay when brought face to face with a case of placenta prævia: they will often resort to the vaginal tampon or colpeurynter when the patient has been bleeding for hours, and is bleached and fainting.

DR. SINCLAIR said that delay is criminal in such cases; that prompt dilatation and delivery would often save the child as well as the mother.

DR. J. R. CHADWICK exhibited

A SPECIMEN OF DERMOID CYST OF THE OVARY.

The patient had had an obscure mental and nervous affection following childbirth which had kept her in bed for three years, during which there had been frequent retention of urine, necessitating the passage of the catheter. On many such occasions a tumor had been felt, at times resting upon the bladder, at others in one or the other lumbar region; it was repeatedly pushed up almost to the ribs, where it was for the moment suspected to be a floating kidney; for long periods it could not be found at all. He was utterly at a loss to account for it, so that he attended the autopsy at the McLean Asylum, where she died of the brain lesion a month ago, with great curiosity. This dermoid cyst of the left ovary, as large as the fist, was found with a pedicle nearly four inches long, which allowed the tumor to be put in almost any part of the abdominopelvic cavity. It contained this wad of hair imbedded in a mass of solidified sebaceous matter, and four small incisor teeth attached to the same alveolar process which is still connected with the wall of the cyst.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY

WALTER CHANNING, M. D., SECRETARY.

THE Society held its twenty-second regular meeting March 4, 1884, at the residence of Dr. Rowe, City Hospital.

After the consideration of such business as came before the meeting DR. W. A. GORTON proceeded to read the paper[2] of the evening, entitled

A CASE OF MONOMANIA.

DR. JELLY said: "I have known something of the patient concerning whom Dr. Gorton's paper is written, for about two years. He had then been sending abusive, obscene, and threatening postals to various people, and was arrested by order of the chief of police. When arrested he fired a pistol at a policeman, the ball lodging in his sleeve and doing no harm. I examined him at some length for two days. His dominant ideas were the wrong way in which society is organized, the oppression of the poor by the rich, and his own personal troubles. A few months later he was arrested again, having again sent threatening postal cards. Then he was noisy and explosive in his behavior, and his language was homicidal and dangerous. He was committed to Taunton. There, after many weeks, he became rather more quiet, and induced his brother to remove him, he giving in writing certain promises which he did not keep. He, after a few weeks, wrote again many very abusive postals, threatened policemen with personal violence, and was finally arrested by order of the police commissioners. When examined he had the same delusions, and was excited, abusive, sullen, and suspicious. He was committed to Danvers. He is really a fine musician, and his brother musicians have borne everything in the way of abuse from him. I think his case a good illustration of monomania. I believe him incurable and a dangerous man, who never should be discharged from the hospital."

DR. FISHER said he first knew the patient whose case Dr. Gorton had reported, about six years ago, and his condition was precisely the same as described. It was the most limited case of monomania he had ever known. He hoped fuller information could be obtained concerning his mental condition at and before puberty. He had been unable to determine whether it was a case of *primäre Verrücktheit* or of *originäre Verrücktheit*. In some of its aspects the case resembled that of Guiteau. The peculiar views and conduct of his brother also found their parallel in the Guiteau case. In their recent books on insanity Dr. Spitzka cited Guiteau as an instance of *primäre Verrücktheit*, while Dr. Hammond classed him as a case of *folie raisonante*. The proper distinction is not always made between these forms, and was not clearly brought out by the reader. In the former the intellectual disorder is primary, and consists in a definite delusion or group of delusions concerning a certain subject. In the latter the affective disorder is primary, and the mania is shown in change of character and conduct, the patient reasoning well on all subjects, and having no delusions. Dr. Spitzka must have regarded Guiteau's claim to inspiration as a genuine delusion, while Dr. Hammond considered it the fraudulent defense of a reasoning maniac.

Dr. Fisher narrated several cases of monomania, and among them referred to the well-known case of G. W. F. Mellen, described by Dr. Rowe. Dr. Mellen believed himself the real president, and the *deus ex machina* of the northern army, which he directed in all its important movements by means of letters to President Lincoln and General Grant. Another case described was that of a merchant who went mad on the subject of Thompsonianism, and wrote crazy pamphlets in its defense, diverting his property from his heirs to found a hospital, converting his own house into an impracticable kind of hospital, for which he never found any patients, and after forty years of this folly ending his days by the exhausting effects of his own prescriptions. He also mentioned a lady who

[1] See page 126 of this number of the JOURNAL.
[2] See page 123 of this number of the JOURNAL.

has for years believed that "Boss Kelly" and Mr. Oliver Ditson were in a conspiracy to defraud her of immense sums due for copyright of some insignificant songs published by the latter. The conspiracy contemplated personifying her indecently on the stage, mobbing, and finally murdering her. Other cases were related illustrating the depressive form of monomania, wherein the depression grows out of the delusion, and not *vice versa*, as in melancholia.

CHICAGO MEDICAL SOCIETY.

DR. D. A. K. STEELE, President.

Regular meeting of July 14, 1884. The Society held a largely attended meeting, and the following scientific business was transacted: —

DR. F. A. MARTIN described

A SUCCESSFUL CASE OF ABDOMINAL SECTION FOR PYOSALPYNX TREATED BY VOLKMANN'S METHOD.

Mrs. T., American, married, aged twenty-seven, weight two hundred pounds, childless, yet desirous of becoming a mother. Four years ago aborted with a three-months fœtus. Consulted the writer one year ago because of suspected pregnancy. She had many of the symptoms of pregnancy, such as morning sickness, enlargement and pain about the mammary glands, enlargement of abdomen, etc.; although she flowed regularly every month for the four months that she considered herself pregnant, yet this secretion was scanty. An ordinary digital examination was made, but no diagnosis was arrived at. Advised the patient to call again, which she did in two months. Examination a second time resulted unsatisfactorily in ascertaining the true state of her condition. Dr. W. H. Byford, who in consultation also made a careful physical examination, was inclined to pronounce her case one of pregnancy, as the patient expressed herself that she felt very decided fœtal movements, together with the other characteristic symptoms that were present, although her menstrual flow appeared scantily each month. Five months subsequently the writer was again consulted. In company with Dr. R. W. Bishop, whilst the patient was anæsthetized, a very thorough examination by bimanual manipulation per vaginam and rectum was made. The small, undeveloped uterus was found crowded close behind the symphysis pubis, and inseparable from a large, firm-walled tumor about the size of a five-months gravid uterus, occupying Douglas's cul-de-sac, and extending upward nearly to the umbilicus, and occupying a position a little to the left of the median line. Owing to the corpulency of the patient and thickness of her abdominal walls, it seemed impossible to make an accurate diagnosis. The uterus measured two and one half inches in length. The patient was again taken to Dr. Byford, and after a careful examination at this visit he pronounced the malady a fibroid tumor of the uterus. However, with commendable conservativeness, he advised that an operation be delayed, although the patient was suffering greatly from pressure of the tumor on the bladder and rectum, from intense backache, and other reflex manifestations. In two months' time her suffering had greatly increased, and she implored that something radical be done to afford her relief.

Operation, May 15th, assisted by Drs. R. W. Bishop, L. L. McArthur, E. L. Hollister, L. T. Potter, S. Black, T. H. Swayne, and E. J. Doering. All necessary antiseptic precautions were observed. Abdominal section was made. Incision eight inches in length, extending from quite near the umbilicus to symphysis pubis. Omentum firmly adherent to the tumor, adhesions covering a space three or four inches in diameter. These were ligated and carefully separated. Not until the omentum was separated was the true nature of the tumor revealed, which proved to be a large dilatation of the left Fallopian tube with thick, firm walls. Tumor so generally adherent to the surrounding tissue that it resembled a fibroid or other solid tumor. Fluctuation was very indistinct, and only by introducing the needle of an aspirator was all doubt of it removed. Upon deeper examination the tumor was found to develop from the left horn of the uterus. On the opposite side of its attachment were the remains of the fimbriæ of the tube and ovary of the left side, the walls of which were muscular in character and very smooth. The operator intended to remove the tumor in its entirety, clamp the small pedicle, and attach it to the inferior angle of the wound, but this was found to be impracticable because the tumor was so universally adherent to the surrounding tissue; the intestines were firmly adherent upon almost the entire surface above. The rectum was so involved as to appear almost as if it were part of the tumor. Hence Volkmann's method of treating abscesses and similar tumors was resorted to, namely, stitching the walls of the tumor or abscess to the peritoneal edges of the abdominal wound, and treating it after union has taken place as an external abscess. The opening in the abdomen was closed with the exception of the lower angle, where about three inches were left patulous. The tumor was stitched to the peritoneal edges of the open wound so that about two inches in diameter of its upper surface remained exposed. The wound, of course, was dressed antiseptically. Examination on the fourth day after the operation revealed the tumor firmly adherent to the abdominal wound. A free incision was now made into the tumor, and a double half-inch drainage tube inserted sufficient to reach the bottom of the abscess. More than a quart of healthy pus was evacuated. The cavity was then thoroughly cleansed with a two per cent. solution of carbolic acid, and again, immediately after, with a saturated solution of thymol to prevent any tendency to carbolic-acid poisoning. Then at night and morning the cavity was cleansed with a solution of corrosive sublimate, one part to three thousand, and the external wound dressed with corrosive-sublimate gauze, one part to two thousand. During the succeeding ten days the patient's condition was favorable, when the temperature suddenly rose to 102° F. Eleventh day it reached 103⅗° F. Respiration irregular and frequent. Pulse 160. Dr. C. Fenger saw the case at this stage. He decided that the lining of the abscess was absorbing purulent matter, which produced the general constitutional disturbance. The opening of the abscess was enlarged by blunt pressure, and the inner surface scraped with a dull curette and cauterized with a twenty per cent. solution of chloride of zinc. Further search revealed an abscess in the thick abdominal walls, which was opened and drained. After this procedure the temperature became normal. She continued to improve until the abscess entirely discharged itself, wound closed, and perfect recovery ensued.

DR. J. H. ETHERIDGE inquired of the author what his diagnosis was before as he stated "it was confirmed while operating." He thought the case had been managed in a most consummately skillful manner, and was much pleased to hear the report. The speaker believes that great advancement has been made in treating these cases to ward off suffering and save life, and that the disease is extremely common, only we cannot diagnosticate it. A physician of Denver introduces the whole hand into the vagina of a patient whilst she is under the influence of an anæsthetic, and by conjoined manipulation he is rendered more able to arrive at a conclusion in the differentiation of this from other disease of the pelvic cavity. He would also inquire what was the result of a rectal examination. This gentleman then presented the history of a case of pyosalpynx, and exhibited the *pathological specimen* that he removed from a case that had recently been under his care. There is nothing particular that needs mentioning about the operation. The case is the ulterior result of perimetritis, which extended and brought about salpingitis. This author stated he had no doubt but what an old gonorrhœa, where it is latent and the discharge scarcely, if at all, perceptible, was often one of the causes of it. A long-continued, chronic orchitis also may produce it. Yet upon inquiring of Dr. A. H. Burr if such difficulty was traced to the husband of the patient in the case he now presented, he was answered negatively. The pathological conditions, as he stated them verbally, are as follows: The right ovary was free from adhesions, and was in a comparatively healthy condition. The right Fallopian tube was inflamed and enlarged. Its fimbriated extremity was so changed and enlarged by previous inflammation that its fimbriæ were obliterated and the canal stenosed absolutely. The fimbriated extremity was free. The left ovary was imbedded in an accumulation of inflammatory exudate, which involved the broad ligament and tube in an indistinguishable and non-separable mass. The left Fallopian tube was inflamed and enlarged throughout its whole length. Its fimbriæ were enmassed and indistinguishable. Its canal was patulous, the distal mouth opening into the abdominal cavity. The outer third of the tube was inseparably agglutinated to the upper surface of the ovary. It was impossible for the free end of the tube to be brought in contact with the ovary because of the obliteration of its fimbriæ, its universal enlargement, and of the complete encapsulation of the ovary. A serous cyst, the size of a pullet's egg, was developed in the inflammatory adhesions of the broad ligament and tube. It was simply a serous accumulation from the perimetritic inflammation. A minute parovarian cyst had commenced, developing beneath and outside of the broad ligament cyst. The condition of the tubes showed that the patient was irremediably and hopelessly sterile. The inflammation and patulous canal (opening into the free abdominal cavity) of the left Fallopian tube constituted the chief source of danger to life. Pus and inflammatory product extruded from the fimbriated extremity was constantly liable to start up renewed attacks of inflammation, which would soon have fatally exhausted her. From this source she has had, doubtless, many minor attacks of perimetritis already, each in turn increasing the exudate which encapsulated the left ovary. The irritation from incarceration of the left ovary in menstruations is probably what led to the menorrhagias which were progressively blanching her. The condition of the pelvic peritonæum which produced a hæmatocele nineteen months ago, together with the salpingitis, perimetritis, and menorrhagia, resulting in progressive anæmia, emaciation, and debility, seemed to demand imperatively the entire removal of the uterine appendages. Death followed in a few days.

DR. H. P. NEWMAN'S experience in these cases was that they are difficult to diagnosticate, and are very troublesome ailments. He thought the successful case as reported was extremely well managed, but would like to ask the writer to explain more minutely his means of diagnosis during the earlier stages of the disease.

DR. L. L. MCARTHUR, regarding Volkmann's method. He had seen it carried out in the treatment of three cases of abscess of the liver and one case of abscess of the spleen with slight modifications. This was done in the service of the City Hospital, and is there approved.

DR. L. T. POTTER inquired, if the neck of the uterus was the normal length would he have been justified in passing a probe earlier? If the tumor pressed the uterus to such degree that the uterus resembled a uterus containing a fœtus?

DR. MARTIN replied as follows: That he did not discover the exact nature of the tumor until the time of the operation, and not until after he had entered the abdominal cavity and introduced an aspirating needle; fluctuation was very indistinct. The tumor seemed very dense, the abdominal walls were at least three inches thick, so that great difficulty was had in trying to outline any form of tumor, even by the minutest examination. The cause of it could not be ascertained. He was in doubt for months whether pregnancy existed or not. Thought perhaps one cause of these tumors might be from stoppage of the uterine orifice of the Fallopian tubes. It was utterly impossible to diagnosticate the case at any stage. Bi-manual manipulation through the rectum and otherwise availed nothing. The rectum was adherent in every direction to the (as supposed) uterus or tumor. Other physicians who saw the case from time to time were in doubt, as was stated in the paper, in their diagnoses, and several different opinions were offered by them. He was afraid to manipulate the womb to great extent or to introduce a probe, as the woman was very desirous of bearing a child, and nearly all the evidence showed that the uterus contained a fœtus, and yet two or three examinations were made before the uterus was found. It was crowded close to the symphysis pubis. The neck of the organ was not in the position it usually occupies when a woman is pregnant.

FRACTURE OF THE CLAVICLE AND ITS RATIONAL TREATMENT,

by DR. S. W. WETMORE, was an unusually carefully prepared and finely illustrated paper. Many of the methods of treating this accident were alluded to. Only two, however, were described minutely and indorsed by him. We append the following synopsis: —

The writer demonstrated first the method introduced by Dr. E. M. Moore, of Rochester, N. Y., having a student on whom he adjusted the dressings. As the literature of clavicular fractures is replete with a multiplicity of appliances having for their object the restoration, coaptation, and retention of the fragments during the process of repair, surgeons during the last half century have very closely followed the ways of the old

masters, but the introduction of the most effective, simple, practical, and satisfactory retentive measures is to be accredited to men of our day.

Causes. After discussing how fractures of the clavicle are most frequently produced, describing the solution of continuity, etc., etc., he thus continued: If the fracture is complete the shoulder is depressed and drawn forward by the action of the pectoral muscles, while the inner portion of the sternal fragment is salient, and sometimes perforates the tissues sufficiently to constitute a compound fracture, though happily this complication rarely occurs. To better comprehend the obstacles with which we have to contend, the reader should be familiar with the origin, insertion, and action of the great pectoral and sterno-cleido-mastoid muscles. The peculiarity of the pectoralis major is that its upper fibres become undermost at its insertion, and its under fibres become uppermost.[1] The clavicular fibres of this muscle are direct antagonists of the sterno-cleido-mastoid, and the further the humerus is carried backward the greater the tension of these fibres and the more perfect the restoration of the fragments. The elbow figure-of-eight bandage meets all the requirements in a simple fracture of the clavicle in the middle third, the one under consideration, by using a shawl, or piece of cotton cloth, or muslin, folded like a "string neck-tie," or cravat, but eight inches in breadth, and two yards long. Placing this wide folded bandage across the palm of his hand, the surgeon then seizes with this hand the elbow of the patient which corresponds with the broken clavicle. The two ends of the bandage hang to the floor. The one falling inward towards the patient is carried upward in front of the shoulder and over the back, making a spiral movement in front of the shoulder. This is intrusted to an assistant. The outer end is then carried across the forearm, behind the back, over the opposite shoulder, and around the axilla. This meets the other end, which may be carried under the axilla and over the shoulder of the opposite side, thus making the figure-of-eight turn around the sound shoulder.[2] This twist, it will be seen, makes also the figure-of-eight turn around the elbow of the affected side. The fore-arm should be sustained by a sling which raises it to an acute angle, in order that gravity may assist in moving the whole arm backward. This is best done by a simple strip three or four inches wide, which may be pinned to the fabric or bandage at the shoulder, or by a sling across the opposite shoulder and behind the back. It will be observed that the bandage, as it passes in front of the arm, does not press on the axillary border of the pectoral muscle, and therefore avoids the objection of the ordinary figure-of-eight. The writer has treated a number of cases during the past ten years by this method with no unsatisfactory result, and heartily commends it to the profession. Its advantages are: (1.) The apparatus is readily obtained and found in every well-regulated household. (2.) It can be applied over the ordinary clothing. (3.) It is readjusted easily when it becomes disarranged. (4.) Any attendant can be instructed so as to readily keep it in place.

The next method described was that of Dr. Louis A. Sayre, of New York City, who treats fractures of the clavicle upon the same principle, namely, *putting the clavicular portion of the pectoralis major muscle on the stretch*, and compelling it to pull the clavicle into place by means of adhesive plaster cut in two strips three or four inches wide (for an adult), one piece long enough to surround the arm and go completely around the body, the other to reach from the sound shoulder around the elbow of the fractured side and back to the place of starting. The first piece is passed around the arm just below the axillary margin, and pinned or stitched in the form of a loop sufficiently large to prevent strangulation, leaving a portion on the back incased by the plaster. The arm is then drawn *downward* and *backward* until the clavicular portion of the pectoralis major is put sufficiently on the stretch to overcome the sterno-cleido-mastoid, and thus pull the inner portion of the clavicle down to its level. The plaster is then carried smoothly and completely around the body, and secured with a safety pin to itself on the back to prevent slipping.

The first strip of plaster fulfills a double purpose: first, by putting the clavicular portion of the pectoralis major muscle on the stretch, it prevents the clavicle from riding upward; and, secondly, acting as a fulcrum at the centre of the arm when the elbow is pressed *downward*, *forward*, and *inward*, it necessarily forces the outer extremity of the humerus (and with it the shoulder) *upward*, *outward*, and *backward*. It is kept in this position by the second strip of plaster, which is applied as follows: Commencing on the front of the shoulder of the sound side it is drawn smoothly and diagonally across the back of the elbow of the fractured side, where a slit is made in its middle to receive the projecting olecranon.

Before applying this plaster to the elbow an assistant *should press the elbow well forward* and *inward*, and retain it there while the plaster is continued over the elbow and fore-arm, pressing the latter close to the chest, and securing the hand near the opposite nipple, crossing the shoulder at the place of beginning; it is there secured by two or three safety pins. When this has been done the deformity will have entirely disappeared, the fractured bone will be accurately adjusted, and as long as the strips of plaster maintain their position no amount of force can displace them. It will thus appear obvious to any one interested in the treatment of this most interesting lesion that the key to its successful management is in making the clavicular fibres of the great pectoral muscle tense, and keeping them so during the period required for repair. *No method can be successful if the humerus be allowed to maintain a perpendicular position.* The plaster method of retention has some advantages over the "neck-tie" bandage method. It is evidently the more secure, firm, and unyielding *at first* (very desirable qualities, particularly with children), and the patient presents a more comely appearance when dressed. Its disadvantages are that the surgeon and particularly the country practitioner do not always have with them the plaster. In hot weather the plaster is apt to excoriate and become irksome and unpleasant. Again, if sufficient traction be made upon the humerus to be of utility as a lever, it necessarily becomes tedious to bear, and the patient tires of the constant strain. The writer did not feel qualified to criticise very closely the plaster method; each of the above two modes has been before the profession for several years, and it is to keep before the

[1] See any work on Surgical Anatomy where a dissection of these two muscles is illustrated.

[2] The reader can easily follow the description herein stated by the adjustment of a shawl or a piece of muslin eight inches in width so that when it is folded upon itself it will be four inches wide; then apply it to any member of his household over the subject's clothing.

medical world those remedial measures which the writer's experience has proven to be the most perfect in their results that the subject is brought forth, although not as advancing anything new.

The paper elicited a free discussion, which was participated in by many of the members.

DR. R. W. BISHOP briefly cited the main points of a case of double fracture of the clavicle that he was recently called to attend. He found a three-cornered piece of the bone broken off that was wedge shaped and turned "up" edgewise under the skin. The best dressing he could devise did not retain the fragment in position, yet the case appears to be progressing favorably.

DR. C. E. WEBSTER visited Bellevue Hospital, New York, last year, and through the courtesy of a friend, who was an interne at the place, he was shown a number of cases of fracture of the clavicle, and noticed that Sayre's method of dressing was applied to but very few of them. Upon inquiry how this happened, the reply was, Sayre's method is applied to a good many of these cases at first, especially if treated in the lecture room, but excoriation results, and the dressings become loose, and others are applied, which the gentleman explained, and which were found to be those generally familiar to physicians.

DR. W. L. AXFORD had listened to the instructions advanced by the author with much interest and pleasure. The solution of continuity or fracture of the clavicle generally occurs at the middle and outer third, and there is deformity either of the acromial or sternal fragment, or both. The philosophy of dressing a fracture of this kind is to raise the outer or acromial end or lower the sternal fragment, or do both. The former is more acceptable, and yet more or less deformity will result. There are a multiplicity of devices by which to dress these injuries. He held it to be axiomatic that the case will pursue its own course with any method, and union take place. He was therefore skeptical of any one method as being better than all others. He would, before closing, like to ask the reader of the paper if his cases that he treated resulted with no deformity?

The CHAIRMAN saw the case cited with Dr. Bishop. There was a comminuted fracture of the bone, and a small piece of spicula with tilted edge that could not be retained in position. The method the author has dwelt so elaborately upon is known here as Dr. R. N. Isham's plan. That is to say, the sound shoulder is made a hitching post and a double figure-of-eight bandage is applied. It gives as good results as any unless it is a plaster-of-Paris dressing, which is irksome and difficult to apply to little children. His success with all methods resulted in more or less deformity. Nature would give admirable results by placing the arm of the affected side in a sling and securing this to a tightly fitting knitted shirt. Long ago he abandoned the adhesive plaster method.

DR. A. B. STRONG was profited by the author's remarks and the illustrations of the paper. The "cravat method" is new to him. Regarding the anatomy of the parts concerned, he said that while the subclavius muscle was not mentioned as having anything to do with the deformity, he thought, however, it did increase it by being excited to contraction, or by its being irritated; the dense fascia also increases the deformity from a like cause. He never saw a dressing give satisfactory results, and thought that placing the arm in a sling, and having the patient lie on a hard mattress, was the best possible known method; all are irksome, but upon a man any kind of appliance would do.

DR. L. H. MONTGOMERY had treated a number of fractures of this bone; all have recovered, and were as strong as before the accident occurred, so far as he knew. He could state positively that in two no deformity existed at the end of a few weeks. One of these occurred in a little boy, being the so-called "green-tree fracture." The other case occurred to a young man eighteen years of age, a clerk; he was anxious that no deformity should result. The speaker told him the only way to avert this was for him to lie in bed for three weeks. He did so for nearly this length of time, with the fracture dressed as any one ordinarily dresses such cases with the addition of a bag of sand over the seat of fracture, and a perfectly satisfactory result was obtained. This method in the treatment of a case of this kind is especially indicated if the patient is a lady.

DR. W. H. CURTIS thought considerable danger might occur from a tightly adjusted sticking plaster dressing around the arm, of strangulation of the brachial artery, especially if it were a long time applied and swelling of the part occurred.

DR. WETMORE closed the discussion, and replied first to Dr. Axford, by stating that he had, as stated by him in the paper, treated a good many cases occurring in children and females by the plan he recommended and no deformity existed. In strong, athletic men he also could recall more than one instance in which there was a satisfactory result and no deformity. During the year 1857 he saw his preceptor treat a case by having the patient (a man) lie in bed upon a bolster, that the weight of the shoulder might pull back the clavicle, and the man recovered perfectly.

The next paper was a very comprehensive one on

RHINOLITHIASIS, WITH A REPORT OF A CASE OF ABOUT FORTY YEARS' DEVELOPMENT,

and exhibition of the specimen, by DR. JEFFERSON BETTMAN.

The following brief synopsis taken from the voluminous article, is here appended: —

The comparative rarity of this affection, the interesting features connected therewith, will be found in a short recital of a case of probably forty years' development. *Status præsens:* The patient is a gentleman, forty-nine years of age, who consulted the writer in June, 1883, for what he termed "chronic catarrh in the head," extending over a period of many years. Of late the annoying symptoms had become more aggravating. The nasal discharge was so copious as to necessitate a daily use of from four to six handkerchiefs. Periodical attacks of hemicrania extending over the right orbital and temporal regions also complicated the case; marked obstruction on the right side of nasal respiration. Physically he is of good dimensions, well proportioned, a picture of florid health. External nose appeared congested and slightly tumefied; borders of the nostrils somewhat excoriated. Introduction of the nasal speculum occasions violent attacks of sneezing. This exquisite hypersensibility of the mucous membrane quite precluded a thorough examination of the nares. There was limited fetor in the expired breath, yet sufficient to be imparted to the nasal secretion; this was also very viscid, slightly flocculent, and filled both nostrils, necessitating removal

ere permitting a survey of the parts. Illuminating the nares, a marked vascularity and thickening of the mucous membrane was noticeable. The tissues covering the inferior turbinated bones were so thickened as to encroach upon and nearly obliterate the fissura respiratoria. . . .

The mucous membrane covering the septum presented almost a fungoid appearance. Both middle turbinated bones were enlarged so as to press upon the septum. The posterior part of the right nasal fossa was filled with an accumulation of creamy looking discharge, and attempts at its removal by a well-directed stream of tepid water were futile. The nasal lumen was so narrowed and encroached upon by the hypertrophied turbinated bone and a co-existing deflection of the septum that it was with difficulty a cotton-wrapped probe could be guided through the parts that were so sensitive. Palpation revealed the presence of a hard grating substance occupying the floor of the right nasal fossa, which was supposed to be necrosed bone as a result of a constitutional dyscrasia. Thorough inquiry in this direction, however, elicited negative replies. To allay the morbid sensibility of the parts a detergent nasal lotion was advised, to be used *ad interim*. In two days' time this proved effectual, as the hypersensibility and tumefied mucous membrane were markedly improved and reduced. Under a strong illumination the position of the foreign body was then defined; it lay on the floor of the nasal fossa in its posterior half and seemed to be impacted between the bony septum and inferior turbinated bone. The exposed surface of the body was rough, uneven, unyielding to the touch of the probe. To dislodge and remove it a pair of strong aural forceps bent at right angles were used. Upon traction being made a firm resistance was met with. The fauces, too, were uncontrollably irritable, defeating all attempts at posterior rhinoscopy. The size of the body had been undoubtedly underestimated. Its removal in toto anteriorly was impossible on account of the narrowed lumen of the nasal passage. Attempts at removing it piecemeal were but partially successful after repeated trials. The feasibility of removing it through the naso-pharyngeal space presented itself. The patient being cautioned not to inspire deeply or swallow, while the operator guarded the faucial orifice, the foreign substance was then forced into the naso-pharyngeal space and in a moment the gentleman spat it out. It was darkish gray, almost black in color, conoidal in shape, and having a very disagreeable odor. Its weight, firm consistency, and the pebble-like uniformity of its unexposed surfaces were sufficient to indicate its calcareous constitution. Irregular in shape, the contours of the concretion conformed to the confines of the surrounding tissues. Its medial surface measured one and a half centimetres in length by one and a quarter centimetre in breadth; the inferior surface one and a half by one half centimetre. The exact weight was one and a half gramme, and imbedded in the mass was a cherry stone. Incidents of the patient's early childhood were vividly impressed upon his memory, but in no possible manner could the presence of the cherry stone be accounted for. Free nasal respiration was fully restored and great relief followed. Subsequently, however, a small mucous polyp high up in the same nostril under cover and almost hidden by the middle turbinated bone was discovered, which was easily removed. . . .

The writer then minutely reviewed the literature on the subject of Rhinolithiasis. Stoerk avers that he has seen but one example of it. No mention of it is made in many works on general surgery. The term was first applied by Demarquay, and our French confrères describe the greater number of cases. Demarquay and Poinsot have written brochures on this subject. The determining cause is the presence of a foreign body which forms a nucleus for the deposition of lime salts. Nasal concretions have, however, developed independently, and where not due to the presence of any extraneous substance, congenital or acquired atresia, stenosis of the nasal lumen favors the retention and subsequent dessication of nasal secretion, and offers a nidus for a concretion. A gouty diathesis may also be a predisposing cause. Virchow describes a "diathesis ossifica" as a cause. This is an entirely different process, yet somewhat similar to the subject under consideration. During an act of vomiting or retching, undigested particles of food may be forced through the naso-pharyngeal space and lodge in the posterior nares, and may be the nidus; barring this possibility, in the foregoing case the concretion may be presumed to have been one of more than forty years' development. . . . Jacquemart lately described a case where the trouble existed over twenty years.

Multiple rhinoliths have been found in rare instances. Their concentric deposition was next described by the writer at considerable length, also their chemical composition. The *symptoms* excited by their presence are frequently not marked, and hence they are doubtless often overlooked, the rhinorrhœa being regarded and treated as catarrhal congestion of the tissues, which often may result in epistaxis. "The chronic vascularity induces a state of hyper nutrition and cellular activity in the surrounding tissues favoring redundancy and neoplastic changes." (Billroth.)

Hemicrania or nervous headache is a noteworthy symptom that is present in many cases. This may be periodical and checked by spontaneous expulsion of minute concretions (Axmann). "Also other reflex neuroses may be present" (Hack).

Posterior rhinoscopy occasionally renders valuable service in this direction. In Jacquemart's case, already alluded to, himself and more than ten consultants had made a previous diagnosis of osteo-sarcoma. A few cases are on record in which rhinoliths were expelled spontaneously, as where the concretions were very small. A stream of hot water injected through the opposite nostril may in some cases prove effective in dislodging the concretion. "Sternutatories may be worthy of trial" (Frankel). The dental drill might render signal service. In post-nasal extraction of a calculus strict precautions must be adopted to prevent it from falling into the larynx.

The remainder of the paper contained many useful hints on the part of the surgeon as well as the patient, and the humane precautions to be taken, but which are often neglected in treating nasal disease.

The paper was discussed by DR. F. O. STOCKTON, who stated that one very simple method the essayist omitted to mention in treating these cases, was by strong pressure from the posterior part of the throat to expel the rhinolith through the anterior nares; this was far the more preferable method of extracting them. The opposite nostril should not be closed when this method is essayed. Another way to remove this form of calculus is by a small loop of iron wire to secure the calculus and rotating the wire upon the stone.

He then cited a case coming under his observation where there was absorption of the small bones, where the stone had pierced some of the small bones of the face. He employed an engine with a diamond drill, or a dental drill with a diamond point, and bored in different directions, and removed it in this manner piecemeal; the mucous membrane and other soft tissues were not in the least injured by the operation. He knew of no other case ever having been treated in this manner. The engine is the invention of Dr. Goodwillie, of Philadelphia, and is used by him in dentistry. The patient operated on was an English gentleman in London, England.

At a late hour the Society adjourned.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

C. B. NANCREDE, M. D., RECORDER.

THURSDAY evening, June 26, 1884. The President, DR. TYSON, in the chair.

SPECIMENS FROM A CASE OF RESECTION OF THE HUMERUS.

Presented by DR. NANCREDE.

Mary D., aged seventeen years, from whom these specimens were removed, received a severe compound comminuted fracture of the left humerus by having her arm wound around the main shaft of a spinning mill's machinery on January 2, 1884. She also at the same time received several severe scalp wounds. Irrigation with bichloride of mercury solution resulted in the salvation of the arm, although in the effort the girl nearly lost her life. At the end of six weeks, no union having taken place, the ends of the fragments being necrotic, I cut down, removed the small fragments here presented, and after sawing off the ends of the main fragments drilled and fastened them together with two stout silver wires. The whole extremity was then put up in a fixed apparatus, plaster, which was not disturbed until irritation of the skin from pressure, etc., required it. Now, at the expiration of about five months, the fragments seem firmly consolidated, with the line of the bone apparently perfect.

MICROSCOPIC SLIDES FROM A CASE OF SPINDLE-CELLED SARCOMA OF THE BREAST.

Presented by DR. G. DE SCHWEINITZ.

I desire to exhibit a few sections this evening cut from a tumor of the breast removed by Dr. John Ashhurst, in the University Hospital. The history of the case, in brief, is as follows: Annie S., married, aged thirty-five, the mother of four children. Family history good. Her own health good until two years ago, when she began to suffer from malaria. The tumor of the breast first began to be manifest one year ago, and grew gradually without much pain until the date of operation, when it had attained the size of an orange. There was no enlargement of the axillary gland. The nipple was not retracted. The growth, to the touch, was hard, and in spots the skin had become adherent, giving rise "to the pitted, somewhat brawny or lardaceous appearance" which is described by surgical writers as rather indicative of scirrhus of the breast. This appearance was sufficiently marked to cause the diagnosis of hard carcinoma to be suggested as probably correct. After removal, when the mass was laid open, both cut surfaces did not appear concave as is usually the case in a scirrhus. Microscopic examination cleared up the diagnosis, for, as you will see by examining the specimens, they show the typical appearances of a small spindle-cell sarcoma. It seemed a good case to illustrate the difficulties sometimes encountered in correctly diagnosticating tumors of the breast, and for this reason I have briefly placed it upon record.

Recent Literature.

Brain Exhaustion, with some Preliminary Considerations on Cerebral Dynamics. By J. LEONARD CORNING. New York: D. Appleton & Co. 1884. 234 pages.

Brain exhaustion, nervous exhaustion, neurasthenia, etc., are the diseases from which just now very many are suffering or think they are suffering. There is a real danger for business men, fashionable women, and those who cannot follow fashion and society, a danger that the cares and worries of life, irregular hours, loss of sleep, and the hundred other unfavorable influences of modern civilization should break down the nervous energy and power. It is well, perhaps, to have these dangers presented anew in order that those not heretofore influenced may be led to see their danger.

Dr. Corning has presented some facts very well, and there are many chapters in his book well worth reading. The incapacity shown by most persons for mental work and great muscular activity at the same time is happily mentioned on page 45. There are many good points in regard to "false educational conceptions and methods," "the exciting causes of brain exhaustion," also as to the influence of emotions, the bad effect of changing life-long business habits, etc.

Many chapters are incomplete, and contain one idea spun out at considerable length instead of giving a more complete but short résumé of the subject. The result is that certain subjects have an undue prominence, and their importance is exaggerated.

The term "cerebral softening" is used several times in its popular sense rather than as a medical term. The popular ideas of cerebral softening are vague, and too many physicians use the expression loosely. In a medical treatise there should be a more exact use of terms. The impression conveyed by the book as a whole, however, is less scientific than popular.

The need of sleep, of brain rest, the general outline of treatment is good. Compression of the carotids is again advocated.

We cannot give the book warm praise as a whole. Much in it has been said as well or better by others; it gives emphasis to facts which are less noticed by other authors, and time spent in reading it would not be wasted.

The Principles of Ventilation and Heating, and their Practical Application. By JOHN S. BILLINGS, M. D., LL. D., Surgeon United States Army.

While disclaiming any intention of writing a systematic manual on the subjects of ventilation and heating for the use of skilled architects or engineers, Dr. Billings has nevertheless presented the subject in a plain and practical manner, the general principles being clearly stated in the opening chapters of the work.

The text is amply illustrated with many diagrams of systems in use in public edifices and hospitals, both American and foreign. The style is clear and free from useless technicalities; formulæ, when necessary, are stated in an intelligible manner. The writer is unsparing in his criticism of faulty methods.

Physicians, architects, engineers, and teachers will all find in it a valuable assistant.

Medical and Surgical Journal.

THURSDAY, AUGUST 7, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

SUGGESTIONS CONCERNING CHOLERA.

SINCE our previous remarks on cholera, in which reference was made to the circulars of the Boards of Health of New York and Illinois and to the steps taken by the State and Treasury Departments at Washington, additional circulars have been issued by the health boards of three New England States — New Hampshire, Massachusetts, and Connecticut. Of the other three New England States, Maine and Vermont have no boards of health, and from Rhode Island we have seen no official announcement of policy. The circulars issued by the three New England States are, in the main, sound, sensible, and timely papers, and, as those Boards have not only sent them to all local authorities concerned in the question of cholera but are ready to mail them to all citizens requesting copies, the local health authorities and inhabitants at large cannot plead ignorance either of the nature of the emergency or of the proper prophylactic measures to be adopted should they fail to prepare themselves for a possible visitation of the disease.

The comparatively moderate character of the epidemic thus far in Toulon and Marseilles, where it first manifested itself, and the absence of the disease thus far as an epidemic from other populous centres in Europe, are not reasons for remitting in any way our own efforts in this country to guard against or prepare for an invasion. Nothing will be lost by a vigilant inspection of vessels and cargoes, whether at the point of departure or arrival, to which suspicion in any way attaches; and a positive gain will in all events arise from whatever measures of cleanliness and general hygiene are enforced in public and private places without and within doors.

Let all classes, the layman as well as the physician, distinctly understand and bear in mind that cholera does not arise *de novo*, but is a filth disease in the sense of being propagated by filth and moisture; that the poison is generally spread by the alvine discharges and absorbed by the alimentary canal; that just as it multiplies most readily in ill-kept places so it is absorbed most readily by ill-kept systems; that though infectious it is not contagious; that whether the active principle be represented by a comma-tipped bacillus or any other micro-organism — and Koch's commission to the contrary notwithstanding, its nature has not yet been demonstrated — the poison finds an abode in drinking-water, on food, in clothing, and may be avoided by sufficient care or destroyed by active germicides.

Bearing these points in mind we may protect ourselves against an epidemic, or, behaving ourselves with discretion in its presence, avoid those lamentable and ridiculous occurrences exhibited where fear and ignorance direct men's actions. Of such occurrences the reports from the South of France afford extreme examples, and the following extract from the London *Lancet* (July 26th) exhibits instructively some of the follies of senseless fumigation and red-tape quarantine: —

"One instance is from Geneva, where impecunious people get into the train, and having given passengers an exaggerated account of the process of disinfection they will have to go through they exchange tickets, and for a substantial consideration they undergo the fumigation discomforts instead of the genuine travelers. The other comes in the form of a protest from the passengers of the homeward-bound steamer Mira from Calcutta. Before touching at Colombo, on April 21st, one of the crew died of cholera. All necessary precautions having been taken the vessel reached Suez, and though sixteen days had elapsed, and all on board remained well, she was ordered to El Tor to perform seven days' quarantine. No proper arrangements had been made for their reception, and a few wooden huts, with some disgustingly offensive privies, afforded the only accommodation available for a large number of first-class passengers of both sexes. Such an arrangement is discreditable in the extreme to the Sanitary Council of Alexandria. But what follows is worse than discreditable. The death had occurred amongst the crew, who occupied an entirely distinct part of the ship from that which was reserved for passengers. And yet it was the passengers who were thus compelled to leave the ship and to go into quarantine, the crew being allowed to remain on board."

ANTISEPTIC MIDWIFERY AT THE DUBLIN ROTUNDA HOSPITAL.

A REPORT of the Dublin Rotunda Hospital by Dr. Macan for the year ending November, 1883, deals chiefly with the application of antiseptics to midwifery. This was the first year that Dr. Macan occupied the responsible position of Master at that well-known lying-in Hospital, and the results of the year's work, although only for one year, unquestionably confirm the wisdom of the antiseptic precautions and methods adopted, whilst supporting the correctness of the theory that puerperal fever is caused by the absorption of animal matter in a state of decomposition, such

matter in one class of cases being introduced from without, and in the other class being derived from the patient herself.

Any one acquainted with the wonderful diminution achieved in the death-rates of lying-in hospitals on the European continent, and especially of those at Prague and Vienna, by a simple attention to cleanliness and antisepsis, need not be surprised at the remarkably favorable results exhibited by this report. Dr. Macan himself, being, as we know, personally cognizant of the continental experiences, could have entertained doubts only as to the feasibility of practically enforcing his methods, but not as to their abstract desirability. The figures given, even though happening to apply to a favorable year, must therefore be regarded not only as a tribute to good judgment, but also to unusual executive ability and good discipline.

Six deaths comprise the total mortality from all causes of 1090 women during the entire time they were at the hospital. This mortality of 0.55 per cent., or one in 181.6 patients, represented, therefore, not only the puerperal mortality, but the total mortality of the puerperal state. The puerperal mortality of private practice is estimated by Dr. Matthews Duncan and Dr. McClintock as not less than one in 120 cases, and the Master of the Rotunda may properly take pride in the reflection that a patient delivered in that institution during the past year ran far less chance of dying than if she had been delivered in her own home by a private practitioner.

To prevent hetero-infection the following are among the important precautions adopted: Students engaged in dissecting are not admitted to the lying-in wards; all students and nurses, before examining any case of labor, are compelled to wash the hands with a nail-brush in a carbolic-acid solution, and to dip them subsequently for half a minute in a solution of corrosive sublimate, one in one thousand; to lessen the necessity of making vaginal examinations abdominal palpation, as at Vienna, is taught each student; every person who examines a woman *per vaginam* must write his or her name on the patient's card, that the origin of an infection may be traced; as soon as the child is born the woman is made to lie on the back to prevent the entrance of air into the vagina or uterus, and the genitals may not be touched with the fingers after delivery except in cases of ruptured perinæum, post-partum hæmorrhage, or retained placenta; before stitching up a ruptured perinæum the vagina is injected with carbolic-acid solution (one in forty); the vagina is irrigated, and the external genitals are carefully washed before every operation, the uterus syringed out afterwards, and a pessary containing ʒiss. of iodoform is then passed to the fundus and left there. All vaginal and uterine tubes are made of glass; a separate tube is provided for each patient, which is kept in carbolic solution and boiled in the same before being used for another; only silver catheters are used, and these subjected to the same treatment.

The prophylactic precautions adopted during labor being sufficient Dr. Macan sees no necessity for any prophylactic antiseptic injections, whether vaginal or uterine, in the puerperal state. The external genitals are washed twice daily with plain warm water and a piece of oakum instead of sponge.

To guard against auto-infection the entrance of air to the uterus is prevented by attention to position; any fetid accumulation is quickly removed; the cavity is disinfected; an iodoform pessary, which exerts its antiseptic action for three or four days, is introduced, and free drainage is provided for.

During the last few months covered by the report the temperature of every case was taken regularly twice daily without indicating any constant rise, even to the extent of one degree, accompanying the first secretion of the milk; these observations tending to show that the temperature curve, in a typical normal case, does not differ from that in the non-puerperal state, and Macan is inclined to regard any temperature above 100° F., except immediately after delivery, as indicative of something abnormal, though it may not always be possible to explain the exact cause of the rise.

Such care as is now exercised at the Rotunda deserves the reward of good results, and we hope such results may be continued there, and become less remarkable only by becoming more common elsewhere.

MEDICAL VERNACULAR.

EVERY physician is obliged to train himself in the oral examination of patients and to acquire something of a lawyer's shrewdness in cross-examination. Sometimes he must draw out an unwilling witness; oftener he must help, without influencing, a patient whose mind is untrained to close examination and nice distinctions, to give as accurate a history as may be of symptoms he cannot appreciate, and of whose significance he is ignorant. Oftentimes the patient's vocabulary is too limited to supply proper words to express his ideas, and sometimes, we fear, the physician is unable to comprehend the poorly-expressed ideas of the willing but incompetent witness who uses words and phrases which have a more or less definite meaning to the narrator, but are unknown to the physician. In fact, a physician connected with a charitable institution of one of our larger cities is brought face to face with every dialect of English and the broken English of the natives of every country on the face of the globe. A study of the pseudo-medical and unusual words in use among the uneducated classes is not without its interest, and by no means devoid of profit to the man desirous of properly understanding the people with whose physical welfare he is concerned.

Some of these lay medical terms are wonderfully descriptive of the condition to which they are applied. Certain of them deserve perpetuation rather than the more modern but less graphic scientific terms for the same trouble. "Lock-jaw" is a common example of these terms. "Show" is almost as good. "Rupture" is moderately good as a descriptive term, but it is doubly good to describe a hernia which goes back with an audible gurgle as a "windy rupture." "Inward fits"

and "dry belly-ache" are well-known terms of great antiquity, as is also the use of "itch" for "scratch." "He has *an upward and downward purging*, sir," will tell many a doctor during the coming weeks, in terms that he cannot misunderstand, that he is summoned to a case of cholera morbus. An "impression on his chest" or, in brief, "an impression" describes a difficulty of breathing from any cause, most commonly used of young children with severe bronchitis. "To heave off from one's stomach" is exceedingly common. Naturally an ineffectual retching is an "empty heaving." Only an Irishwoman can attain the poetic height of "heaving an empty stream."

In this category should also be included "the windy dropsy," which, if it means anything, ought to be an emphysema. This term has been met with but once, when a young woman was heard to inquire whether her mother's complaint was the "water dropsy" or the "windy dropsy."

A baby worn down by diarrhœa, unable to hold itself upright, is well described as "kinder *slack*."

The curious tendency to eke out a scanty vocabulary by frequent and vain repetition is by no means confined to the heathen nor to various forms of worship, but shows itself particularly in attempts to make plain to the medical man the symptoms which the patient considers he ought to understand so easily without explanation.

Ignorance of the proper meaning or the derivation of words leads to curious reduplications, as, for instance, "pneumonia of the lungs," "dysentery of the bowels;" the "yellow jaunders" is a similar reduplication, but the use of the adjective of color is justified, as it allows differentiation from the more terrible "black jaunders."

Some of these words seem to have acquired a perverted meaning when used in reference to matters of health. "Better" has acquired a meaning synonymous with well; for example, a physician asking his patient if he is better is answered in the negative; examination showing a decided improvement he says, "You are certainly very much better," and is answered, "Well, perhaps I am most better, but not quite," and he will announce his final recovery by saying that he is "all better."

A curious instance of this use of the comparative is found in William Black's Shandon Bells. The speakers are supposed to be exceptionally well-educated people. "I was almost forgetting to ask how your aunt is, — better I hope." "Oh, I think so. I think she is almost quite better." . . . "But she is not ailing now?" "Oh no, scarcely at all."

Backwoodsmen and sailors occasionally ask to have their teeth "hauled." One old lady took great delight not very long ago in telling her doctor that her leg did not "render," that is, discharge, so much as before commencing treatment.

The most interesting of these words are those which have dropped out of the written language and survive only in the vernacular. Most of these words have a history, and, like so many of the expressions of the vernacular, have seen better days; Archbishop Trench would describe them as drawing out a miserable existence in reduced circumstances. Many of them serve to perpetuate the pathology of former days or continue an inaccurate nomenclature. Many an interesting lesson in the history of medicine or the history of the language may be learned from them. One of the most curious of these survivals is the King's Evil, which has lost its royal title, and survives as simply an *evil*, a term occasionally heard applied to suppurating glands of the neck. The old word "poll," which survives in a few technical phrases, is still used by people of Celtic origin.

"Rising," for a swelling, occasionally used now for an abscess within the auditory meatus, survives from the time of King James's Version of the Bible. "Corruption," found in King James's Version as indicating putrefaction, now refers to pus. "Beal" is very commonly used to express supparation. Rab's master said, "Our Ailie's skin 's ower clean to beil." To speak of a pharmacist to-day as "a 'potecary" marks the speaker as an individual of little learning, but that form is found in Chaucer.

Certain words show their derivation and are more expressive than their commoner forms. To *peaceify* a crying child seems a more maternal operation than simply to pacify it, and *ilement*, to one accustomed in his youth to the old form ile, is certainly a better word than unguent, while *restful* is certainly one of the most pleasing adjectives that can be applied to a surgical apparatus. If the surgeon finds the next day that the injured member has "swoll" during the night and made the patient "unrestful," he will perhaps pardon the poor fellow for *dis*remembering his instructions.

Different classes of men have peculiar forms of speech, drawn often from their habits of life. There are many peculiar expressions among sailors. The colored people always designate pain as "misery," and not unfrequently describe it as "lingering." "The almonds of the ears" is used by some colored people for the tonsils, a natural expression for Germans, as it is but a translation from their native language, but how a colored man should come to use it is not so plain.

It is amusing and even pathetic to hear the attempts of a foreigner, whose English has been picked up in the forecastle or "long shore," and consists principally of oaths, to express intelligibly his ailments. Such a patient will rub his hand over his abdomen and say, "Something bites me here", and in reply to attempts to elucidate the matter will explain by comparing the severity of his pain to the place of future punishment.

There are many curious misunderstandings and mispronunciations. Certain individuals are "caustic" in their bowels, while others with injured feet "gimp" as they walk. "Too regular in the bowels" is an occasional synonym for diarrhœa. One of the most puzzling problems for an ordinary tongue is to express one of a pair of twins. "He 's the one half of a twin," "the half of a pair of twins," are some of the forms of expression used. A complaint often made is

that "the palate is down," which refers to any trouble in the fauces, but most appropriately to a lengthening of the uvula. How to explain the complaint of the woman who said that "the spoon of her breast was down, that the doctor had tried to put it up but could not," remains a mystery. "A flag in the breast" means an induration of any kind. "A chamber-doctor" is an obstetrician. "Whittle" is in common use for whitlow.

A story in a recent newspaper makes a valuable addition to anatomical nomenclature, and illustrates the habit of patients to attribute curious sayings to their doctors. According to the newspaper a man in a little town in Connecticut caught his foot in a mowing machine, and the accident restored to him the power of movement in the ankle-joint, which had been lost forty-six years before, when his foot had been caught under a roller that was in use in moving a barn. "Every one at that time thought he would lose his leg, but after some six months he so far recovered that he was able to walk, going upon the toe of that foot. He consulted a physician, who told him that the heel-pin had been driven up between the bones of the ankle, but advised letting it remain, as breaking it up would cause great pain. It was a bad place to work, and they might not get it right after all. So for forty-six years he has walked with a limp, but it would seem as though that mowing machine wheel had done the business, and brought the heel-pin to its right place."

Undoubtedly many more of these words have histories of their own which individuals learned in the history of the language could retail. Doubtless the new English Dictionary on Historical Principles, by Dr. Murray, now in process of compilation, will throw light upon the use of many of these words and make their study more easy and entertaining.

"The right word is always a power and communicates its definiteness to our action," and the study of the difficulties of the unlearned ought to aid the physician in the use of simple and unambiguous language.

MEDICAL NOTES.

— We are glad to state that at the request of the Board of Trustees of the Massachusetts General Hospital Drs. H. J. Bigelow and R. M. Hodges have withdrawn their resignations from the staff of visiting surgeons.

— The National Board of Health held an annual meeting in Washington, Wednesday, July 30th, and elected the following officers: President, Dr. James L. Cabell, Virginia; Vice-President, Dr. Stephen Smith, New York; Secretary, George E. Waring, Esq., Rhode Island.

— The British Medical Association held its annual meeting at Belfast, Ireland, July 29th to August 1st. The flourishing condition of the Association is shown by the fact that the increase in membership during the last year amounted to 1000, and the number of names now on the roll of the Society is 12,000. Addresses were made by Dr. Waters, the retiring president, and Dr. Cuming, the president elect. Numerous papers were presented in the various sections by distinguished writers.

— The announcement is made that the British Government have appointed a cholera commission consisting of Dr. Klein, F. R. S., and Dr. Heneage Gibbes, who have been directed to proceed forthwith to India to pursue a scientific inquiry into the nature of cholera. It is understood that these gentlemen will act in conjunction with the commission nominated a few weeks ago by the Indian Government for the same object. "In the prosecution of their labors," remarks the *Lancet*, "Drs. Klein and Gibbes may be assured of the hearty good wishes of all Englishmen, and the results of their mission will be awaited with great interest. The government in arriving at this decision have only done that which ought to have been done twelve months ago; and it cannot fail to touch the national pride that the country which has the largest interest in arriving at a sound conclusion upon the nature of this disease should have allowed Germany and France to have preceded it in the research. It is better, however, to be late in the field than to ignore the value of such an inquiry altogether."

— Professor Jäger, of Vienna, the distinguished ophthalmic surgeon, has recently died.

NEW YORK.

— At the suggestion of Dr. Cyrus Edson, of the health department, an ordinance has been passed forbidding the use of vessels made of brass, lead, copper, or other metallic substance in the sale of beer, soda water, syrups, and other beverages or flavoring materials, on account of the danger of the formation of compounds detrimental to health. An investigation into the character of the lining of the soda-water fountains of Brooklyn is at present being made by Health Commissioner Raymond.

— The executive committee of the commission appointed at the recent session of the Legislature to investigate the sanitary condition of the tenement houses of New York commenced the work of inspection during the last week of July. It consists of Drs. Moreau Morris and Abbot Hodgeman, Charles F. Wingate, sanitary engineer, and William P. Esterbrook, superintendent of buildings.

— A public meeting was held in Hoboken on the 27th of July for the purpose of taking some action in securing a better and purer supply of drinking water, which for the past ten years has been obtained from the Hackensack River. Professor Leeds, of the Stevens Institute, who had been employed by the mayor to make an analysis of the water, stated that he had found in it large quantities of vegetable matter, which, while it might not be injurious to health, rendered it objectionable. This accumulation of vegetable matter, he thought, was due to the recent heavy rains, and he expressed the opinion that the evil would not be abated until the reservoir was thoroughly cleaned. This one of the engineers in the employ of the water company promised would be done, and the meeting adjourned

without taking definite action in regard to the matter.

— A conference was held July 30th between Col. Emmons Clark, secretary of the Board of Health, Dr. Day, sanitary superintendent, and Superintendent Walling, of the police department, with a view of adopting a plan of police surveillance over all vessels landing cargoes on the water front of the city, in order to prevent the unloading of infected goods which may have been smuggled through quarantine. It was held in consequence of the discovery that a vessel, which had been passed through quarantine, on the declaration that there were no rags on board, was landing rags at a Brooklyn dock.

— The annual appropriation by the Legislature of $20,000 for the assistance of the worthy blind in New York City has just been distributed. Those who are eligible to the benefits of this fund are men and women who have resided at least two years in the city, who are totally blind, and who have never been inmates of a public institution, and its object is to encourage them to help themselves and keep out of almshouses and asylums.

— From the annual report of the Railroad Commissioners it appears that during the last year twenty-four persons were killed and ninety-one injured by accidents on the street railways. Of the number killed, six were passengers, two were employees, and sixteen were persons in the streets. Of those injured, forty-six were passengers, and forty-five persons in the streets.

— Mollie Lee, who is said to be the only full-blooded Indian squaw of the Shinnecoch tribe now living, is more than a hundred years old, but is in feeble health. She is a resident of the Indian reservation near Southampton, Long Island.

Correspondence.

TREATMENT OF ASIATIC CHOLERA.

MR. EDITOR, — The German commission, of which Dr. Koch was chairman, announce that Asiatic cholera is due to a living bacillus existing in the intestines. It also announced that these bacilli cannot live in the presence of acids. If these views are accepted it would seem that cathartics accompanied with acids are strongly indicated in this disease.

When Dr. George Johnson, of King's College Hospital, London, advocated the castor-oil treatment, in 1855, his views were very generally pronounced fallacious. Now it would seem to be established that his treatment was based upon a pathology very nearly correct. His method was to give the castor oil in doses of an ounce every hour, or thereabouts, till the character of the discharges changed, at the same time not neglecting other treatment. He severely denounced the use of astringents and brandy in such cases because he believed that the intestines contained a "morbific agent" which must be removed.

I once conversed with a gentleman who had passed through a cholera epidemic in Havana, Cuba. He had seen great benefit from the use of large doses of olive oil. This would also be rational treatment in view of the pathology.

Instead of advising the public, therefore, to use brandy and laudanum in this disease, as I see the daily papers doing, a contrary treatment should be urged. We should advise full doses of castor oil or larger doses of the olive oil. At the same time the patient should take an acid in sufficient quantity to overcome for the time being the alkalinity of the intestinal juices. For this purpose vinegar, lemon juice, or, better, the dilute hydrochloric acid might be given.

These views seem to follow logically the announcements of Dr. Koch and his colleagues.

Yours truly, WM. H. LATHROP, M. D.

LOWELL, MASS., *August* 4, 1884.

Miscellany.

THREE DOCTORS IN FICTION.

THE fact that such writers as Mr. Howells, Miss Phelps, and Miss Jewett should within four years so carefully study what is practically the same subject, makes it worth while to compare their stories closely, says the *New York Evening Post*. Passing any question of relative literary merit, and taking them all as widely read and much liked books, there are remarkable points both of likeness and difference between them. In the first place no one of the heroines works for her living. Dr. Breen "was rich enough to have no need of her profession as a means of support." Of Dr. Zay it is said "loftily" by the old lady, "Doctor is quite independent of her practice." Between Dr. Leslie and her aunt, Nan Prince is sure of a fortune. They are all beautiful. Mr. Howells gives us "the tender curve of her cheek, the soft round of her chin." Dr. Zay "was the eidolon of glorious health." "There was a sort of golden halo round Nan's pretty head." In costume and carriage they are all of the choicest. Dr. Breen only studied simplicity, but "she did not finally escape distinction in dress and manner." Dr. Mulbridge "grew more and more conscious of her elegance and style, now that she stood before him." Dr. Zay has almost a superfluity of violet muslin, of skin of seal and leopard; she has "a glorious poise," and moves "with a swift and splendid motion." As Nan walked up the broad aisle of St. Anne's Church "the rows of heads all looked commonplace by contrast. . . . There was something so high and serene in Anna Prince's simplicity and directness." They are further alike that each has had the best special training for her career that the times afforded. That they count two out of three for homœopathy may go for what it is worth.

As to motive, we come to marked differences. Dr. Breen turned to her study in the heart-sick reaction from the treachery of her friend, the faithlessness of her affianced. She is watching her first patient at Jocelyn's. Dr. Zay "always had a taste for science, she inherited it besides." Her father was a physician, but died when she was only fifteen. She has practiced four years in a Maine village. "She don't fall short of three thousand every year of her life," is the assertion. Nan's father, whom she never knew, was also a physician, but it was her constant sympathy, her affectionate admiration for her guardian, the "country doctor,"

which determined the restless longing of her finely endowed nature toward the same career as his own. Either motive is a likely one, but the last is the more natural and more healthful.

Once more a difference, Mr. Howells may not quite have intended it, but his heroine first turns to her lover in the profound dejection of the discovery of failure in herself — her heart, her strength, are not equal to her demand upon them. Dr. Zay's lover gains his advantage when she is physically exhausted with a night of watching and a struggle with delirium tremens. Does this mean that neither would have yielded if she had been strong? Nan stands waiting in all the success of her hope. Yet Miss Jewett has felt obliged to supply even her with another motive than the love of her profession for refusing marriage. Nan believes that inherited tendencies bar her from it. "*Qui s'excuse, s'accuse.*" Does not this amount to an agreement among the three that home and hope of children draw a woman more strongly than anything else can.

Space fails us for the inferences this extended comparison suggests. Supposed cases are not logical arguments: they are only illustrations; but when independent illustrations strikingly agree, it is more than an accidental coincidence. To put the case fully in all its bearings, Dr. Breen should be successful; Nan's lover should be a strong, masterful, yet tenderly sympathetic man. But the great fact remains, no one yet ventures to represent a woman struggling as most men struggle to gain a footing in the professions. No one ventures to present her without the attractions that are distinctly feminine, and the want of which (that is, those that correspond) would be only a temporary hindrance to the man. There is a deep and — considering the future — an almost painful significance in the conviction, put concretely in Dr. Breen's case, implied throughout "Doctor Zay," and stated so plainly and so appealingly by Nan, that the duties of home, as falling upon the wife and mother, are incompatible with the practice of a profession. We believe all experience proves it, and what may seem examples to the contrary are either where the possession of wealth or powers so exceptional as to be outside all rules have smoothed the way, or where the profession has been taken up after the home had been made, its traditions developed, its happiness secured.

REPORTED MORTALITY FOR THE WEEK ENDING JULY 26, 1884.

Deaths reported 3660 (no reports from Buffalo and Milwaukee): under five years of age, 2006; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases), 1333, diarrhœal diseases 986, consumption 357, lung diseases 164, diphtheria and croup 86, whooping-cough 61, measles 51, scarlet

fever 39, typhoid fever 36, malarial fevers 42, cerebro-spinal meningitis 15, erysipelas seven, small-pox five, puerperal fever four, yellow fever one. From *measles*, New York 33, Chicago 12, Brooklyn and New Orleans, two each, Philadelphia and St. Louis one each. From *scarlet fever*, New York 10, Philadelphia, Chicago, and Boston six each, St. Louis three, Cincinnati and Pittsburg two each, Lawrence, Somerville, Salem, and Gloucester one each. From *typhoid fever*, New York 10, Baltimore, Cincinnati, and New Orleans four each, Chicago and Nashville three each, Philadelphia, Brooklyn, and St. Louis two each, District of Columbia and Charleston one each. From *malarial fevers*, New York 11, New Orleans 10, Brooklyn and St. Louis eight each, Baltimore and Charleston two each, Nashville one. From *cerebro-spinal meningitis*, New York five, Chicago three, Lowell and Fall River two each, Philadelphia, Nashville, and Haverhill one each. From *erysipelas*, New York five, Philadelphia two. From *small-pox*, New Orleans five. From *puerperal fever*, Brooklyn and Chicago two each. From *yellow fever*, New Orleans one.

Cases reported in Boston: scarlet fever 53, diphtheria 14, typhoid fever 14, and measles one.

In 112 cities and towns of Massachusetts the total death-rate for the week was 21.54 against 17.68 and 15.35 for the previous two weeks.

For the week ending July 5th in 170 German cities and towns, with an estimated population of 8,753,688, the death-rate was 29.1. Deaths reported 4902; under five years of age 2734 consumption 613, lung diseases 498, diarrhœal diseases 354; diphtheria and croup 147, whooping-cough 64, measles and rötheln 57, scarlet fever 51, typhoid fever 41, puerperal fever 15, small-pox (Metz two, Dresden one) three. The death-rates ranged from 15.1 in Rostock to 44.9 in Aachen; Königsberg 29.4; Breslau 36; Munich 32.1; Dresden 31.2; Berlin 32.7; Leipzig 25.6; Hamburg 29; Cologne 35.7; Frankfort a. M. 30.9; Strasburg 27.7.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 14th, the death-rate was 22.2. Deaths reported 3726: acute diseases of the respiratory organs (London) 206, diarrhœal diseases 495, whooping-cough 103, measles 102, scarlet fever 71, fevers 51, diphtheria 22, small-pox (London 21, Liverpool six, Sunderland two, Sheffield, Hull, and Cardiff one each) 32. The death-rates ranged from 11.1 in Plymouth to 25.9 in Halifax; Birmingham 18; Bradford 21.4; Leeds 23; Leicester 20.4; Liverpool 24.9; London 24; Manchester 23.3; Nottingham 25.2; Sheffield 18.2; Wolverhampton 20. In Edinburgh 16.5; Glasgow 23.1; Dublin 22.3.

For the week ending July 12th, in the Swiss towns, there were 36 deaths from consumption, diarrhœal diseases 26, lung diseases 16, typhoid fever nine, diphtheria and croup five, scarlet fever two, whooping-cough one, erysipelas one, puerperal fever one. The death-rates were, at Geneva 15.3; Zurich 15.8; Basle 11.6; Berne 23.3.

The meteorological record for the week ending July 26th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT UNITED STATES ARMY FROM JULY 26, 1884, TO AUGUST 1, 1884.

HEAD, JNO. F., colonel and surgeon. Ordered to Portsmouth, N. H., to meet the Greeley party, and consult upon the proper course of treatment, with a view to the entire restoration to health of Lieutenant Greeley and the men of his command. S. O. 177, paragraph 14, A. G. O., July 30, 1884.

WRIGHT, JOSEPH P., major and surgeon. Sick leave of absence extended three months on surgeon's certificate of disability. By paragraph 12, S. O. 176, A. G. O., July 29, 1884.

MCELDERRY, HENRY, captain and assistant surgeon. So much of paragraph 12, S. O. 165, A. G. O., July 16, 1884, as assigned him to duty in Department of the East is revoked, and he is ordered to report in person to the Surgeon-General of the Army for duty in connection with World's Industrial and Cotton Centennial Exposition at New Orleans, La. Paragraph 12, S. O. 173, A. G. O., July 25, 1884.

FINLEY, J. A., captain and assistant surgeon. Granted leave of absence for one month, with permission to apply for one month's extension, to take effect about September 1, 1884. Paragraph 2, S. O. 91, headquarters Department of Texas, July 22, 1884.

REED, WALTER, captain and assistant surgeon. Relieved from duty at Fort Sidney, Neb., and ordered for duty as post surgeon, Fort Robinson, Neb., relieving Assistant Surgeon Henry McElderry, U. S. A. Paragraph 2, S. O. 62, headquarters Department of Platte, July 22, 1884.

NEW ENGLAND METEOROLOGICAL SOCIETY.

THE Council of the New England Meteorological Society desires to secure the coöperation of all persons in New England interested in its subjects of investigation, with the purpose of encouraging the observational study of meteorology and of uniting into a common plan the labors of those who make a practice of keeping records of the weather. The Council proposes at the outset to establish a simple system of observations under the direction of Prof. Winslow Upton, of Brown University, including for the present only records of rainfall and temperature range: other subjects may be added in the future, but it is thought advisable to attempt nothing more in the beginning than can be properly discussed and published. Among those who have already signified their willingness to join the Society's undertaking physicians form a considerable number; from their technical training and habits of close observation they will make members of especial value, and the Council therefore hopes to enlist among its observers all who have already kept weather records or who are willing to undertake such records under its auspices. A circular giving the plans of the Society in more detail may be obtained by addressing W. M. Davis, Secretary, Cambridge, Mass.

DIED. — At Jamaica Plain, August 1, 1884, Benjamin Franklin Wing, M. D., M. M. S. S., aged seventy-nine years.

MEDICAL DELUSIONS.[1]

BY ALBERT DAY, M. D.

The wonderful influence of imagination in the cure of disease is well known, and it has become a fruitful resort for all kinds of vile quackery and blasphemous pretentions. A motion of the hand or a glance of the eye will throw a weak and credulous patient into a fit, and a pill made of bread, if taken with sufficient faith, will operate a cure better than all the drugs in the Pharmacopœia. It is related by a medical historian that the Prince of Orange, at the siege of Breda, in 1625, cured all his soldiers who were dying of the scurvy by a philanthropic piece of quackery which he played upon them, with the knowledge of the physicians, when all other means had failed. The prince sent the physicians two or three small phials containing a decoction of camomile, wormwood, and camphor, telling them to pretend it was a medicine of the greatest value and extremest rarity, which had been procured with very much danger and difficulty from the East, and so strong that two or three drops to a gallon of water would impart a healing virtue. The soldiers had faith in their commander; they took the medicine with cheerful faces, and grew well rapidly. They afterwards thronged about the prince in groups of twenty and thirty at a time praising his skill, and loading him with protestations of gratitude. Many thousand of instances of a similar kind might be related, especially from the history of witchcraft, and even in our own time we see the work of religious pretenders as exhibited by the blasphemous shows at the gatherings at Old Orchard and other places annually. Such scenes are a disgrace in this age while they could be tolerated in the times of universal ignorance, before the laws of psychiatry and kindred sciences were developed. A few centuries ago the mummeries, strange gesticulations, and barbarous jargons of witches and sorcerers, which frightened the credulous and nervous woman, brought on all those symptoms of hysteria and other similar diseases so well understood now, but then supposed to be the work of the devil not only by the victims and the public in general, but by the operators themselves.

In reading the history of nations we find, like individuals, they have their whims and their peculiarities, — the seasons of excitement and recklessness, when they care not what they do. We find that whole communities suddenly fix their minds upon one object, and go mad in its pursuit; that millions of people become simultaneously impressed with one delusion, and run after it until their attention is caught by some new folly more captivating than the first. We see one nation suddenly seized, from its highest to its lowest members, with a fierce desire for military glory, another as suddenly becoming crazed upon religious scruples, and neither of them recovering their senses until the craze has shed rivers of blood and sowed a harvest of groans and tears to be reaped by its posterity. At an early age in the annals of Europe its population lost their wits about the sepulchre of Jesus, and crowded in frenzied multitudes to the Holy Land; another age went mad for fear of the devil, and offered up hundreds of thousands of victims to the delusion of witchcraft.

It is my purpose, however, to deal with medical delusions chiefly of the past and present, although I can but speak briefly upon this topic, for volumes would be required to record all these delusions with all the crimes and follies they have entailed upon our race. I will not go back to the ages of demonology, when all disease was considered the work of demons (and this delusion is still believed to an extent shameful to the present enlightened age), but will briefly recite the history of a few medical delusions over which people have gone mad within the last century or two, dwelling especially upon that of the Perkins tractors.

It is not a century since the Perkins delusion with its metallic tractors turned the heads of many wise and good people. Dr. Elisha Perkins, of Plainfield, Connecticut, invented his tractors (an identical set of which I now exhibit before you), and began a practice with them about the year 1796. One part is composed of steel, and the other seems to be of brass or some metallic compound. The operation consisted in uniting the large ends and then drawing the sharp points over the diseased parts, no incision being made. This being done several times completed the operation.

I hold in my hand a book containing the letters received by Dr. Perkins, giving the wonderful cures which had been performed by the metallic points. The persons giving these certificates were clergymen, physicians, and other distinguished persons. Some of these certificates are evidently false, and therefore the persons writing them did so under the most positive delusions.

EXTRACTS FROM LETTERS TO THE AUTHOR OF THE METALLIC DISCOVERY.

Pierpont Edwards, Esq., District Attorney for the State of Connecticut.

New Haven, *October* 7, 1796.

Dear Sir, — I should have written you last week, had I then been able to ascertain certain facts, the rumour of which I had heard. A Mrs. Beers, a near neighbor to me, the wife of Eber Beers, and daughter of Capt. Samuel Huggins, of this town, had been, for fourteen weeks, exceedingly distressed with the rheumatism, to such a degree, that for fourteen weeks previous to the 29th of last month, she had not been able to walk across her room even with the crutches, save only once, when she made out, with the assistance of crutches, to hobble part of the way across her room. On the 29th of September last, she procured a set of your Metallic Substances, and in less than an hour after she had begun to use them, in the manner directed by you, she rose from her chair, and walked about the house, and on the next day she went abroad to her neighbors, having thrown aside her crutches. I have this day paid her a visit, in company with her father, and Timothy Jones, Esq. who lives in the street where she resides and directly opposite to her residence, and with Captain Abel Burrett, who is her next neighbor, and lives within eight yards of her door. I requested her to relate her case over in their presence, which she did, and these gentlemen all, with one voice, supported from their own knowledge, her story. It is a duty which you owe yourself and the world to promulge this event.

I am respectfully, your most obedient servant,

Pierpont Edwards.

N. B. She says her fever has left her, her appetite has returned, and she is in a fair way to be restored to perfect health.

James Glover, Esq., Norwich, County of Tioga, State of New York.

September 19, 1796.

Sir, — Having lately purchased a set of your patent instruments to keep in my family, I have used them with great success on a person scalded with boiling lie: a man by the name of Welch, who was at work in my potash, when boiling down the lie, some of it flew into one of his eyes, which soon became very

[1] Read before the Suffolk County Medical Society, April 26, 1884.

much inflamed, and swelled to such a degree, that he could not open it, and remained in that situation, for the space of three days, when after a few minutes operating with your patent instruments, he was able to open it, and with two operations only, his eye was almost entirely free from pain and inflammation, and in a short time was perfectly well, although so badly scalded, he had almost despaired of its ever recovering.

JAMES GLOVER.

Mr. Samuel Satterlee.

WILLIAMSTOWN, *November* 3, 1796.

Sir, — I was called on in the evening, by a gentleman with a cancer on his lips, which caused a severe inflammation in every part of his face; I furnished him with a set of your Metallic Instruments, until the morning following, when he returned so enraptured with their effects, that he readily purchased a set.

I am &c. SAMUEL SATTERLEE.

Mr. John Punchard.

SALEM, *October* 19, 1796.

Sir, — I have operated repeatedly with your Metallic Points and have succeeded in removing rheumatic pains, agues, pains in the head, face, side and burns to my astonishment, and to the astonishment of all present. I cured a man burnt with powder, in less than half an hour, with the Points, without any other application. JOHN PUNCHARD.

Bezaleel Woodward, Esq., Professor of Philosophy and Mathematics, Dartmouth College.

HANOVER, NEW HAMPSHIRE, *September* 19, 1796.

Sir, — I have made use of your pointed Metallic Instruments in various disorders, and besides universally abating and generally removing pains in the head, face, teeth, &c., by application of them, I have found them useful in the salt rheum. Only one opportunity has presented for an effectual trial — that has cured the patient by three applications, which being noised abroad, sundry persons affected with that disorder, have been at my house this week, to have the operation performed on them; and the disorder has abated on the first application, so that the present prospect is, that cures will be effected for them, by further use of the Instruments. A violent pain proceeding from a sprain in the foot, has, by a few minutes application of the Instruments, been removed so as not to return.

I have the honor to be, Sir, your most obedient and humble servant, BEZALEEL WOODWARD.

Gen. Elihu Marvin, Member of the Connecticut Medical Society.

NORWICH, *December* 20, 1796.

Sir, — Since I have been in the use of your patent Metallic Points, which is about four months, I have, by way of experiment, made use of them in cases of inflammations of almost every kind, and in subjects, of all ages and descriptions, and as might be expected, with various success. One fact, however, I am fully convinced of (in opposition to former prejudices), viz. That in a variety of circumstances, a proper application of them is capable of operating a change in the human frame, which I can no more doubt, because I cannot assign a satisfactory philosophical reason therefor, than I can doubt the operation of opium, because, the properties of that gum, by which, and the modus operandi, in which it produces sleep, are to me wholly unknown. I am confident reasoning a priori, would as soon establish one fact as the other. Cases in which the points have, in my practice, appeared successful, are such as burns, headaches, agues in the face, ophthalmics, pains in the limbs, breast, and sides, and in cynanche tonsillaris, yet candor requires I should say, success in these cases has not been universal.

One case of cynanche tonsillaris, or common inflammatory quinsey, I will relate to you: — I visited a young man late in the afternoon, found him exercised with all the usual symptoms of that disease; such as general inflammatory diathesis, the tonsils so tumefied as to be nearly closed together. His throat and neck externally enlarged, a constant discharge by spitting a glairy mucus, and complaining of excessive pain in the parts: by his account, these symptoms had been increasing for about three or four days. His mother informed me that he had not swallowed anything for thirty-six hours, except three or four spoonsful of water, in which toasted bread had been soaked. I could not learn that any means had been used for his relief, except keeping within-doors, and making some external applications. I applied the Metallic Points externally in the usual way; very soon the spitting sensibly decreased. After some time, he observed the pain was wholly gone on one side, and much lessened on the other. I then directed him to make trial how he could swallow; he took a tumbler of sweetened water, and drank it with little difficulty, and immediately ate about half a pint of custard. I then left him, with directions to repeat the operations occasionally; and, in the intervals, to keep the throat covered with some emollient poultice. On visiting him the next day, I found him sitting at the fire, roasting oysters, and eating them without difficulty; he observed he was well. I made every enquiry, to discover whether the swelling had not burst, but could not learn anything from him which gave the least reason to think it had. I left him a dose of purgative pills, which he swallowed without pain, and in a few days regained his usual health.

One case of pain in the side, occasioned by the patient, while unwell, being exposed to a cold, damp atmosphere, attended with great interruption of locomotion and difficult respiration, was completely relieved by a few minutes' application of the Points. With every sentiment of esteem, I remain your sincere friend, ELIHU MARVIN.

Dr. Samuel Willard, Member of the Connecticut Medical Society.

STAFFORD, *August* 6, 1796.

Since I returned to Stafford, I have made trial with your Metallic Instruments with very happy success, in a case of acute rheumatism, which had, for a long time, baffled all the remedies to which I myself and two or three other physicians had advised.

The wart which I burned down when at your house, gave me no trouble as to any sensation of fire, after you operated on the inflamed part; I felt a soreness for several days after, but the soreness was no greater than would have arisen from the destruction of so much skin from any other cause. It argues great folly to condemn any innovations, or new improvements in the arts and sciences, without due investigation. This is a kind of treatment, however, which you have already experienced, and which you must expect still to experience.

I am &c. SAMUEL WILLARD.

John Vaughan, M. D., State of Delaware.

CHRISTIANA, *July* 14, 1796.

Dear Sir, — I have operated in a few cases only, with your instruments, for but few have offered since I possessed them. One case of nervous or hysteric headache, perfectly cured — a case of odontalgia relieved. The third a young man, who had fallen ten or fifteen feet on the edge of an open ended hogshead, and received a considerable contusion in the umbilical region, with tumefaction. I bled him three times to little purpose. But after about two minutes operation with the instruments, he exclaimed in extasy, "I am well — I am well — my pain is gone." The pain, however, returned in a less degree, but in thirty or forty minutes went off entirely, and he went to work as usual.

I am &c. JOHN VAUGHAN.

Rev. Dr. Morse, of Charlestown.

December 9, 1796.

Dear Sir, — I have made a faithful trial of your patent Metallic Points in a number of cases — such as burns, pains in the head, teeth, face, ears, side, back and limbs, arising from colds, and in one or two instances rheumatic pains have been relieved by them; and in one instance the painful effects of the sting of a wasp were entirely removed. In some cases I have been unsuccessful, particularly in a burn, where[1] oil had been previously applied, and in the tooth-ache, where the teeth were[2] very defective. On the whole, I believe the discovery to be a very useful one; I wish it cordially all imaginable success.

I am &c. JEDEDIAH MORSE.

Rev. Walter King.

NORWICH, *October* 6, 1796.

Sir, — The fame and utility of your patent instruments have become subjects of so much notoriety and speculation, that almost all pained people are desirous of making trial of them. Their efficacy within my knowledge, appears to be increasing. I am more and more confirmed in the benefit of the discovery, and cannot think but they will continue as long as the pains of the human body shall need them.

I am &c. WALTER KING.

[1] In the transfer of the patent right, one of which accompanies each set of instruments, are specified, the several differences in which this treatment is useful — the mode of operation and the circumstances which prevent the general effects. It is there observed — "The efficacy of the means is prevented by all oily and greasy substances."

[2] It may not be reasonably presumed, that a cure could be made on teeth which were very defective.

Rev. Dr. Robbins, of Plymouth.

September 24, 1796.

Dear Sir, — Several persons, since you left us, have experienced immediate relief, in various complaints, by the Metallic Points.

I operated, day before yesterday, on a man's hand, which was prodigiously swelled and painful, by a wound he received on the back of it, which he neglected and got cold in. It was much inflamed; but was relieved by that single operation. The swelling subsided, and the inflamation went away, so that he went directly to work on board his vessel. He told me the last night it gave him no trouble. I am &c.

CHANDLER ROBBINS.

Rev. Dr. Stillman, of Boston.

October 6, 1796.

Dear Sir, — I feel myself much obliged to you for the important service you have rendered to Mrs. Stillman's eyes, after a distressing inflammation of eight months. If, through too much exercise, or being exposed to very cold air, a degree of inflammation returns, it is removed in a few minutes again, by the application of your points. I have in my walks among the sick, made use of them repeatedly with success; and cannot but think they will be of important benefit to mankind.

I am &c. SAMUEL STILLMAN.

Rev. Mr. Balch.

GEORGETOWN, *May* 16, 1797.

Dear Sir, — A neighbor of mine, Mr. James Connor, was sorely afflicted with an inflammation in his left eye, and a pain in his head. His eye appeared like a ball of blood, and all the contiguous parts were much inflamed, and of a bloody color. I saw your Metallic Points applied to the affected part with such success, that, in the space of about ten minutes, he declared the pains were gone — he has told me since, he never felt any inconvenience from it afterwards.

Several of my neighbors who have been afflicted with pains, have testified in favor of your tractors.

That you may succeed in promoting the happiness of the human race, is the wish of,

Sir, your humble servant, STEPHEN B. BALCH.

CERTIFICATES.

Capt. William Ladd.

I hereby certify, that for twelve or fourteen years past, I have been frequently exercised with severe paroxysms of the Gout. In the fall of 1795, I had a violent attack of this disorder, which had confined me to my room for six or eight days. At this time, when my foot was very much swelled, inflamed, and in such extreme pain, especially my great toe, that I could not walk nor set my foot on the floor, Doctor Hopkins called on me, and operated on my foot, with an instrument, as he said, according to Dr. Perkins' directions. Within five minutes the pain and inflamation ceased, so that I walked with ease. The swelling, within twenty-four hours, subsided so that I put on my shoe; and this foot, in two days became as well as the other. The pain has twice returned since, but has been soon removed by the same application. WILLIAM LADD.

Rev. Samuel Hopkins, D. D., Newport, R. I.

NEWPORT, *August* 17, 1796.

I the subscriber, hereby certify, that I performed the operation on the foot of Capt. William Ladd, which is by him above related, and am witness to his being relieved and cured by said operation. I have had credible information of other persons being cured of pains by the same means in this town.

SAMUEL HOPKINS.

Rev. William Patten.

The subscriber is a witness to the cure of Capt. Ladd as above related, and has reason to believe that in various other instances, persons in this place have been relieved, by the same application, from pains in the head, eyes, &c.

WILLIAM PATTEN.

NEWPORT, *August* 17, 1796.

Mr. Constant Freeman, Master of the Almshouse, Boston.

This certifies, that Docter Elisha Perkins, of Plainfield, Connecticut, visited the poor house of this metropolis, about three weeks ago, and performed operations on several patients, with his celebrated Metallic Points; among whom he performed his operation on one John Patterson; he had been in the poor house for six months, with the rheumatism — Two months of which he was confined to his bed — four months he had hobbled about with crutches, when Docter Perkins performed the operation; since which, he has thrown aside his crutches, and walks only with a staff, which he uses, not for the rheumatism, for he has none, but merely for a support, as his thigh bone was then and still remains dislocated.

Nancy Blake was also cured by the Doctor of the rheumatism in the small of her back, which had constantly afflicted her for more than three years. It has not yet returned. I myself cured Benjamin Ross of the rheumatism in the small of the back and hip. This was ten days ago; it has not yet returned.

Lewis Dumeth, a Frenchman, was operated upon by the docter, for the rheumatism in his lower extremities, which had confined him to his bed and crutches for months; but no sooner was he operated upon, than he threw aside his crutches — walked about the house — has walked about the town since, and has had no return of the rheumatism in either leg.

CONSTANT FREEMAN.

BOSTON, *October* 5, 1796.

Mr. Edward Hill.

I Edward Hill of Dorchester, in the County of Norfolk and State of Massachusetts, hereby certify that I have been afflicted with the rheumatism and gout at times, for nine years past, and at length to such a degree as to be unable to walk. But upon the application of Dr. Perkins' Patent Metallic Instruments, I was in the course of two days, so recovered as to be able to walk without any pain. EDWARD HILL.

Perkins also invented a medicine, an antiseptic, and, being anxious to try it in yellow fever, he went to New York in 1799, where then the disease was prevalent, and after four weeks of unremitting toil he himself died of the fever.

About the time of the popular excitement occasioned by the wonderful cures by the "tractors," Dr. Benjamin Douglas Perkins, son of Elisha, went to England, the wonderful cures by the magnetic tractors having preceded him. He settled in Leicester Square, London, where he proposed to make good the fame of his father. He then took out a patent for the wonderful "tractors." The most wonderful stories soon obtained general circulation, and the press groaned with pamphlets all vaunting the curative effects of the metallic tractors, which were sold at five guineas the pair. Perkins gained money rapidly; gouty subjects forgot their pains in the presence of this new remedy; the rheumatism fled at its approach, and toothache, which is often cured by the mere sight of a dentist, vanished before Perkins and his marvelous steel-plates.

The benevolent Society of Friends, of whose body he was a member, warmly patronized the invention. Desirous that the poor, who could not afford to pay Perkins five guineas, or even five shillings, for his tractors, should also share in the benefits of that sublime discovery, they subscribed a large sum and built a hospital, called the "Perkinean Institution," in which all comers might be magnetized free of cost. In the course of a few months they were in general use, and their lucky inventor in possession of five thousand pounds.

Dr. Haygarth, an eminent physician of Bath, recollecting the influence of imagination in the cure of disease, hit upon an expedient to try the real value of the "tractors." Perkins' cures were too well established to be doubted, and Dr. Haygarth, without gainsaying them, quietly, but in the face of numerous witnesses, exposed the delusion under which the people labored with respect to the curative medium. He suggested to Dr. Falconer that they should make wooden tractors, paint them to resemble the steel ones, and see if

the very same effects would not be produced. Five patients were chosen from the hospital in Bath upon whom to operate; four of them suffered severely from chronic rheumatism in the knee, ankle, wrist, and hip, and the fifth had been afflicted for several months with gout. On the day appointed for the experiments Dr. Haygarth and his friends assembled at the hospital and with much solemnity brought forth the fictitious tractors; four out of five patients said their pains were immediately relieved, and three of them said they were not only relieved but very much benefited; one felt his knee warmer, and said he could walk across the room; he tried and succeeded, although on a previous day he had not been able to stir; the gouty man felt his pains diminish rapidly, and was quite easy for nine hours, until he went to bed, when the twitching began again. On the following day the real tractors were applied to all the patients, when they described their symptoms in nearly the same terms. The same experiment was tried in other hospitals with the same results.

An account of these matters was published by Dr. Haygarth in a small volume entitled, Of the Imagination, as a Cause and Cure of Disorders, exemplified by Fictitious Tractors.

The friends of Perkins were unwilling to confess they had been deceived. They found at last that no one believed in them. The Perkinean Institution fell into neglect, and Perkins made his exit from England carrying with him about ten thousand pounds to soothe his declining years in the good city of Philadelphia.

Thus, for the time, magnetism was laughed out of England. It would seem that the Medical Society of Connecticut was purely orthodox, medically speaking, for we find on the records of the Society the following declaration made, at an adjourned convention of the Medical Society of the State of Connecticut, holden at Hartford on the 17th day of May, 1796: —

Voted, It having been represented to this Society that one of their members had gleaned up from the miserable remains of animal magnetism a practice consisting of stroking with pointed metalic instruments, the pained parts of human bodies; giving out that such stroking will radically cure the most obstinate pains to which our frame is incident — causing false reports to be propagated, of the effects of such stroking, especially when they have been performed on some public occasion, and on men of distinction also, that an excursion has been made abroad, and a patent obtained from under the authority of the United States, to aid such delusive quackery, that under such auspices as membership of this Society, and patent above mentioned, the delusion is progressing to the Southward which may occasion disgrace to this Society and mischief abroad; wherefore this Society announce to the public, that they consider all such practices as barefaced imposition, disgraceful to the faculty and delusive to the ignorant; They therefore direct their Secretary to cite any member of this Society, practicing as above, before them at their next meeting, to answer for his conduct, and render reasons why he should not be expelled from the Society for such disgraceful practices.

At a subsequent meeting the following vote was passed: —

Whereas Dr. Elisha Perkins, a member of this Society, having obtained a patent from under the authority of the United States for the exclusive privilege of using and vending certain pointed Metallic Instruments, pretending they were an invention of his own; and also, that they possess inherent powers of curing many diseases which is contrary to rules and regulations adopted by this Society interdicting their members the use of nostrums, Therefore

Voted, That the said Elisha Perkins be expelled from the Medical Society of the State of Connecticut.

This delusion was practiced in a generation not remote from the present. What is called magnetism has in ages past been a stronghold for quacks, and is to this day among certain classes. We hear men and women "*rubbers*" boasting of their magnetism, and even advertising themselves as doctors with special powers and gifts for healing. Of late these delusions have taken a new form, and even now we have Faith Schools in our midst. They blasphemously take the name of religion, and practice their impositions upon the weak-minded and gullible public. They pretend to be but little lower, if not a little above, angels, and contract with the Almighty for the healing of diseases. In these times we behold a ray of light. Science is coming forth in shining garments, with her hands unstained with human blood; when she shines in full effulgence these imps will hide in the dark recesses as the owls and bats do at noonday.

Did time permit, it would afford me pleasure to give a more full history of the magnetizers, whose feats have been regarded by the populace as *wonderful*, and so they are to one who cannot or does not understand the laws of mind.

One who understands psychological law can well comprehend why it is that a sick person who has little or no power to resist impressions from surroundings can be made to feel better or worse, when the bedside is surrounded by the praying band, who offer up one after another earnest prayers with certain gesticulations well known to the fraternity. The laws of psychiatry now explain the wonders of mental phenomena which were once attributed to supernatural agencies. The merest tyro now understands various phenomena which the wisest of old could not fathom.

The school-boy knows why, upon high mountains, there shouldon certain occasions appear three or four suns in the firmament at once, and why the figure of a traveler upon an eminence should be reproduced of gigantic stature upon another. We all know the strange pranks which imagination can play in certain diseases; that the hypochondriac can see visions and spectres; and there have been numerous cases in which men were perfectly persuaded that they were *tea-pots*, and I have cases under my care frequently who think they are somebody other than themselves. One thought he was his mother, another thought he was his horse, etc., etc. Science is lifting up the veil and rolling away all the fantastic horrors in which our forefathers shrouded these and similar cases. The man who now imagines himself a wolf, a dog, or a horse, or his mother, is sent to the hospital instead of to the stake, as in the days of the witch and devil mania; the earth, air, and sea are no more peopled by the grotesque spirits that were once believed to haunt them. It seems to me the duty of every physician to deal honestly with his patients, and, as far as possible, to remove these delusions from the public mind; when this is done our insane asylums and mad-houses will be less full, and mankind will understand better how to handle nature's laws, and use them not for a curse, but for a blessing.

— The model "grateful patient" is the London art dealer, Mr. King, who at his death left half a million dollars to St. George's Hospital, and more than half a million dollars to his medical adviser, Dr. Roper.

THE PITCH OF THE PERCUSSION SOUND.[1]

BY LEONARD HUNTRESS, JR., M. D., OF LOWELL.

In this paper I shall not have time to dwell long on the subject of pitch in general, as I wish to confine my observations to two special matters which seem to me of interest.

The pitch of the percussion sound has been regarded as of little consequence until lately, and I do not think that sufficient prominence is given it to-day, except by a few writers. Auenbrugger barely alludes to the pitch of the percussion sound. Neither Laennec nor Piorry mention it. Locher pronounces it chimerical. Skoda considers the variations in pitch as of little practical value, although he admits that "it occasionally happens that the presence of tubercles in the upper part of the lung may be diagnosticated by the different pitch of the percussion sound over the corresponding part of the other lung."

American and English writers lay no special emphasis on the importance of the pitch. French writers generally slight the subject, although Woillez considers it of more importance than the intensity or the quality of the sound. He says: "I place the pitch at the head of the important characteristics of the percussion sound." And again: "If up to the present time its importance has not been understood, it is because it has not been studied apart from its intensity."

Niemeyer expresses himself thus: "Although formerly this distinction (between high and low pitch) was treated in such a neglectful (stiefmutterlich) manner, it is of much use to modern workers in percussion."

Stern says: "To-day men of training are better fitted to distinguish differences of pitch than differences of sonorousness and intensity, and therefore it is evident that many medical investigators of abnormalities of sonorousness and intensity really perceive only the change of pitch."

The four elements of the percussion sound which should be studied with reference to diagnosis are quality, pitch, intensity, and duration. I know that this is an unusual classification, but I am sure that it is the correct one. I have found it in but one of all the writers I have studied on this subject. Some writers recognize only intensity and quality as elements of the sound; others add to these two a third, pitch. Seitz alone considers the duration of the sound of sufficient importance to classify it as a distinct element.

The duration is not to be confounded with the pitch of the sound. The latter depends upon the number of sound-waves which strike the tympanum of the ear in a given time. The former depends on the length of time these waves continue to strike upon the tympanum, and of course can be considered only when the sound is produced by a stroke or blow, and not where the sound is caused by a continuedly applied force, as in wind and string instruments. The duration of the sound depends in part, to be sure, on the pitch, a high-pitched sound being, *cæteris paribus*, of shorter duration than a low one. Two sounds of the same pitch may, however, differ greatly in duration, as in the case of the long-vibrating peal of the church bell as compared with the short beat of the drum, even though the pitch be alike in both cases.

[1] Read before the Massachusetts Medical Society, June 11, 1884, and recommended for publication by the Society.

The conditions, other than the pitch, which influence the duration of the sound refer in part to the substance of the body percussed, the duration being in direct proportion to the elasticity and homogeneousness of this body. The medium surrounding the body percussed also affects the duration of the sound. Strike a bell suspended in the air gently, and note the duration of the vibration. Now immerse the bell in water and strike it more forcibly, so that the intensity of the two sounds shall be equal, and see how much sooner the vibrations cease. A third factor is the movability of the point or points of support by which the body percussed is held in place. The duration is directly proportional to the movability of this point. So *one* reason for the long-continued vibration of the church bell is the fact that it hangs suspended in the air, with nothing but its weight to prevent it from swinging with every breeze.

I would urge upon instructors in physical diagnosis the importance of teaching duration as well as pitch, as an essential element of the percussion sound.

Of the three commonly recognized elements of the percussion sound, quality, pitch, and intensity, I admit that in many cases the quality may be the most important and significant, and differences in quality in two sounds may be so marked as to be more easily distinguished than the difference in pitch or intensity. I think it, however, no more than fair to claim that as between the two latter the pitch of the percussion sound is of more aid to us in diagnosis than the intensity.

If, for example, you are comparing the two sides of the chest, it is impossible to percuss them with equal force. Even if it were possible, no one could be sure from which side the louder sound is elicited. The force of the percussion stroke affects the pitch comparatively little. The difference in pitch is something that any one with (I will not say a musical ear, for happily our ears are all with few exceptions musical) an ordinary ear can distinguish. Let any one strike a note on a piano twice in quick succession, the first time somewhat more forcibly than the second, in the hearing of a company of unselected persons, and there will probably be by no means a unanimity of opinion in regard to the intensity of the note. Let him now strike two different notes, and probably the listeners can all distinguish the higher from the lower one. They certainly can if the two notes differ much in pitch. In the percussion sounds of the thorax it is not uncommon to have two sounds for comparison at least a fifth apart.

There are two characteristics always existing in the pitch of a sound, which aid us in our determination. A high sound is, as we have seen, of comparatively short duration. It is also of harder tone. A low sound is of longer duration and of softer tone. This always assists us in determining the pitch of a sound, whether we recognize the aid it affords us or not.

The first point to which I call your attention is the difference in pitch between the percussion sound of the right infraclavicular region and that of the left in the healthy thorax.

Several years ago I was taught by Dr. Guttmann, of Berlin, who follows Traube in this regard, that the pitch is higher on the left than on the right side of a healthy chest. All the instruction I had previously received on the subject had been the reverse. I therefore determined to ascertain what was generally taught

by good authorities, and to make some experiments for myself.

To show the teaching of Dr. Guttmann, I will quote from his Handbook of Diagnosis: "In the normal thorax differences in the pitch of the percussion sound at different parts may be recognized by a cultivated musical ear; thus, on the right it is usually found to be deeper than on the left, though occasionally the reverse condition is met with."

I will compare this statement with the teaching of Dr. Flint in his work on the Respiratory Organs. Referring to the infraclavicular region, he says: "In the majority of persons the resonance on the left side is somewhat more intense, the vesicular quality is more marked, and the pitch lower than on the right; per contra, the resonance and the vesicular quality are less and the pitch higher on the right side."

I have studied the literature of the subject with some care, and I generally find but little said concerning this point. By inference most of the authorities represent the two sides as alike in pitch; for example, when every region of the thorax is carefully discussed, and such a special point as the difference in pitch between the inner andr and outer parts of each infraclavicular region is brought out, no allusion whatever is made to a difference between the two sides.

We should not expect this point discussed by so early a writer as Auenbrugger, but I will call your attention to what he has to say bearing upon it: "If a distinct sound, equal on both sides and commensurate with the degree of percussion, is not obtained from the sonorous regions above mentioned (the thorax), a morbid condition of the parts within the chest is indicated." Corvisart, in his Commentaries, says: "It is a circumstance too obvious to be much insisted upon, that the percussion must be strictly similar and equal on both sides. The least sonorous side is certainly diseased." Of the American writers, DaCosta agrees with Flint. The others are silent on the subject. Most of the English writers whom I have consulted say nothing. Dr. R. Douglas Powell, however, affirms that "in the clavicular and infraclavicular regions the note should be even on the two sides as low as the third rib on firm percussion." French writers generally ignore this point, although Mailliot says: "The lungs percussed with equal force on the right and left side give the same result on one side as on the other, from the apices down to the fourth rib." German writers, so far as I have studied them, are also silent here, except Traube, Guttmann, and Seitz. The two former generally find the right side of higher pitch than the left, while Seitz finds that "in the axillary region in many cases the sound is relatively deadened (pitch raised) on the right side," thus agreeing rather with Flint.

On which side should we expect, *à priori*, to find the pitch the higher?

The height of the sound depends upon the volume of the air-containing body percussed (the lung), and also upon the tension of the chest wall and parenchyma, being inversely as the volume and directly as the tension. We may represent this by $H = \frac{T}{V}$. There is, I think, no doubt of the correctness of this formula, although Skoda says that the pitch is dependent entirely upon the quantity of air in the lungs, and Woillez thinks that he has demonstrated by the spiroscope that the pitch is not influenced, at least in every case, by the tension.

Other conditions may affect the pitch; as, for example, the condition and thickness of the chest walls, and the size and substance of the organs lying in juxtaposition to the diaphragm.

Flint, with regard to the infraclavicular, and Seitz, with reference to the axillary region, both think that the increase in intensity and the lowering of pitch on the left side may be accounted for, at least in part, by the transmission of sonorousness from the tympanitic stomach.

I do not see how Flint can consistently make use of this argument, for two reasons: First, the tympanitic sound which he thinks tends to a lowering of the pitch here, he asserts emphatically is always higher pitched than the normal vesicular resonance. Secondly, he teaches in the same work that whenever the intensity of the percussion sound is morbidly increased (here by the tympanitic sound, as he says), the pitch is always raised.

All of the conditions, aside from the tension of the chest wall and parenchyma and the volume of the lung, exert upon the pitch a comparatively slight influence, I think.

There is no uniform difference between the tension of the two lungs recognized by authorities and laid down in text-books. There is a difference in the volume, the right lung being the larger. Hence we should expect to find the pitch lower in the right lung in the majority of cases. Should we find the reverse to be true, we should conclude that the tension was greater on the right than on the left side, and, too, that the difference in tension exceeded the difference in volume.

I have been experimenting upon this matter for several years, and have given careful attention to the work. It is needless to say that all the subjects examined were in good health, and that special care was taken with reference to pulmonary disease. All cases of deformed and unsymmetrical thoraces were discarded; also all abnormally large or small ones. I percussed in every case both with and without the plexímeter, and I attended to two points which are often overlooked in comparing the percussion note of the two sides. First, care was taken in every case to percuss on points equally distant from the sternum, for in the regio-infraclavicularis externa the pitch is higher than in the regio-infraclavicularis interna. And secondly, percussion was made at the same period of the act of respiration, always at the close of a full inspiration.

Referring to the formula $H = \frac{T}{V}$, in inspiration, both numerator and denominator are increased, but the increase in tension of parenchyma and chest wall is greater than the increase in volume of the lung, and as a consequence the pitch is higher at the time of full inspiration than at any other period of the act of respiration. At the close of a forced expiration the pitch is slightly lowered, although Stokes says: "A full inspiration makes the sound clearer, full expiration the contrary, but they both raise the tone a little, they render the pitch higher. Why is this? For the simplest reason in the world, — both actions tighten the drum. They strain the walls of the chest and render their vibrations quicker, and therefore the sounds higher." This, by the way, is the only allusion to the subject of pitch that this writer makes in his work on the chest.

I have had opportunity to examine only two hundred subjects; not enough, I know, to determine the matter satisfactorily, but still enough, I think, to be of

interest to you. The persons were mostly men, thirty only being women. They were all between the ages of twenty and forty. I divided them, with reference to the results obtained, into five classes: (*a.*) Those in whom no difference was found in the pitch of the two infraclavicular regions. (*b.*) Those in whom the pitch was slightly higher on the right. (*c.*) Those in whom it was slightly higher on the left. (*d.*) Those in whom it was markedly higher on the right. (*e.*) Those in whom it was markedly higher on the left.

I will say here, that whenever I thought there might be a slight difference of pitch, but was in doubt about it, I placed the case in class *a*.

The result was as follows: —

(*a.*) No difference	72
(*b.*) Slightly higher on right	71
(*c.*) Slightly higher on left	26
(*d.*) Markedly higher on right	23
(*e.*) Markedly higher on left	8

At first glance this result might seem to be of little significance, but I do not so consider it. Out of two hundred cases in but seventy-two, or but little more than one third, is the pitch equal on the two sides. In ninety-four cases, nearly one half, the pitch is higher on the right than on the left. In thirty-four cases the reverse is true.

Now what is the practical bearing of this, supposing the work to have been well done, and considering the cases sufficient in number to be of value?

In the first place, a difference in pitch — and a difference in pitch means a difference in intensity and quality as well — at the apex of either lung, unless decidedly marked, does not necessarily indicate disease on the side where the pitch is higher. According to my investigation there is a difference in nearly two thirds of the cases. This, however, is not generally taught.

Secondly, although the right side is much oftener high-pitched than is the left, still out of two hundred cases we have thirty-four, seventeen per cent., in which the pitch is higher on the left. So, although it is much more significant to find the left lung showing dullness on percussion at the apex than the right, yet this by no means is proof of disease, as I think is generally taught by those who make any distinction between the two sides.

While I was conducting these experiments, a friend made the criticism that to have the result satisfactory a resonator should be used, so that the pitch could be accurately determined. I do not agree with him. In that way every variation of pitch could be discovered, to be sure, and probably a slight difference would be noticed in nearly every case, but it would be of no practical value. What I desired to show was what could be discovered by an ordinary ear, — an ear musically uncultivated.

. . . . . .

There are so many unsettled questions in medicine that it would seem worse than useless to call attention to any point simply because authorities differ concerning it. If we were to do that we should have our hands full. But there is so much loose writing, especially concerning strictly scientific matters, in even the best medical works, that I think a protest now and then is needed. I desire to call your attention to the pitch of the tympanitic sound.

Dr. Flint, in his work on the Respiratory Organs, teaches that the pitch of the tympanitic percussion sound is always higher than that of the normal vesicular resonance, and he affirms that there is no exception to this statement. In his Manual of Percussion he says: "If there are any exceptions they are very few."

Dr. Loomis, in his Physical Diagnosis, says that the pitch of the tympanitic sound is lower than that of the normal vesicular resonance.

These statements, unaccompanied by any explanation, are taught as facts by two of our most widely read writers. They are diametrically opposed to each other, and I think I can show that, although the latter writer is, from a scientific stand-point, nearer the truth than the former, they both offer good examples of loose and incorrect writing.

The normal vesicular resonance is a good illustration of a non-tympanitic sound. The sound elicited from pulmonary cavities under certain conditions, and also the sound obtained by percussing the intestines or stomach when not too tensely inflated, are good examples of a tympanitic sound. The latter is a clear, ringing sound, with a musical tone, the sound-waves striking upon the tympanum of the ear at regular periods. The non-tympanitic sound is not a musical sound, the waves striking the tympanum irregularly.

Percuss a freshly removed sheep's lung without inflation, and you obtain a clear musical tympanitic sound. Inflate the lung to the degree of tension maintained in life, and the sound becomes less clear, non-musical, and non-tympanitic. Here the pitch is raised. Or take a pig's bladder, just barely filled with air, with no stretching of the membrane, and on percussion the sound is clear and tympanitic. Now inflate the bladder until the walls are tense, and the percussion sound is non-tympanitic, with a higher pitch.

According to Skoda and Niemeyer, and in fact according to authorities generally until quite recently, the relaxation of the chest well and parenchyma was considered as the chief if not the only necessary condition of tympanicity of the pulmonary percussion sound, and the tension of these parts the sole cause of non-tympanicity. Tension of the membrane often destroys the tympanicity, to be sure, as the two examples just given illustrate, and as is seen in meteorismus of the bowels. In all these examples the pitch is raised. Tension does not, however, necessarily destroy the tympanitic sound, as is seen in the case of the drum. With this example before him, how could Skoda say that the stretching of the membrane necessarily destroys the tympanicity of the percussion sound? In many pulmonary cavities the tympanicity and also the pitch are dependent on other factors than the relaxation of the surrounding walls.

I have not space, however, to dwell on theories as to the cause of tympanicity, under all the different conditions with which it is met. I will call your attention to certain pathological conditions in which the percussion sound is tympanitic, and consider the question of pitch in each case.

Those conditions which favor retraction of the lung tissue often give rise to a tympanitic percussion sound, just as we have seen that the lung when removed from the thorax and allowed to assume its natural uninflated volume gives a clear musical tympanitic sound.

There are several pathological conditions under this head, but I will allude to only one, which is sufficient for illustration.

In moderate pleuritic exudations the lung above the level of the fluid shrinks in volume, and when this

retraction reaches a certain point, which is variable in different cases, the percussion sound is tympanitic. In this case the pitch is lowered as the tension is diminished. Here the pitch of the tympanitic sound is lower than that of normal vesicular resonance.

If all cases where the sound is tympanitic could be thus easily disposed of, Dr. Loomis would be justified in his broad statement, for here the two sounds compared are both elicited from lung substance, and the tympanitic one coming from a lung of diminished tension is in consequence of lower pitch.

Without attempting to classify all the conditions which give rise to a tympanitic percussion sound, I will speak of a class of cases which are very different from that just discussed, and which obey different laws with reference to their pitch. I refer to the tympanitic percussion sound of pulmonary cavities.

In the first place, a cavity is either shut in completely by its walls, or it communicates by an opening with the adjoining tissue. If it is completely occluded, the air within cannot be set in vibration so as to produce an audible sound if the walls are stiff and unyielding. If the walls are sufficiently elastic to admit of the production of a distinct sound from the cavity, tympanicity will be present only in case the walls are not too tense.

The tympanitic sound obtained from a completely occluded cavity with elastic walls in a state of relaxation obeys the same law of physics with reference to pitch as the non-tympanitic normal vesicular resonance. The height is directly as the tension and inversely as the volume.

If the cavity communicates by an opening with the adjoining tissue, the sound may be tympanitic with either elastic or unyielding walls. If the walls are stiff and inelastic, the pitch of the percussion sound depends upon the volume of the cavity and the diameter of the opening of communication, being inversely as the volume and directly as the diameter of the opening. If the walls are elastic, the pitch of the sound depends on these two factors in just the same way, and also upon the tension of the walls, being of course in direct ratio with the tension.

There is also a general law with reference to the elasticity of the walls, that the pitch of cavities, *cæteris paribus*, is in inverse proportion to the elasticity of the walls. If a cavity is sufficiently long and narrow, that is, if in form it is a tube rather than a cube, the pitch does not depend upon the volume of the cavity, but upon the length of the air-vibrating column, being in inverse proportion to this length.

It is true that the tympanitic sound of the abdomen is higher pitched than the normal vesicular resonance. This is not because it is tympanitic. You could with more truth say it is in spite of that fact. We have seen that in tympanicity from lung retraction the pitch is lowered. We have also seen that in the case of the tympanitic sound of pulmonary cavities the pitch is sometimes high and sometimes low, according to the elasticity and tension of the walls, the diameter of the opening of communication, the volume of the cavity, or the length of the air-vibrating columns.

Perhaps Dr. Flint arrives at his conclusion by simply comparing the sound of a tympanitic abdomen with the normal vesicular resonance; and Dr. Loomis may arrive at his by thinking with Skoda that the sole cause of tympanicity is relaxation and decrease of tension of the tissues.

A CASE OF CHYLOUS DEPOSIT IN THE ABDOMEN.[1]

BY FRANKLIN NICKERSON, M. D., OF LOWELL.

THE subject of this sketch has been deaf and dumb from his birth, and his wife became so at the age of four years, the result of some injury. The two children of this union can both speak and hear. Our patient is fifty-five years old. He was born in Westford, Mass., in which place and Lowell he has spent his life. He has lived in Lowell thirty-two years, and for the past thirteen years in Bachelder's Place, which leads out of Walker Street at a point not far from Pawtucket Street, — a locality which is sufficiently healthy. Up to fifteen years ago he had worked in a bedstead factory. Since then, till a year and a half ago, his occupation had consisted in finishing doors, in which a good deal of heavy lifting is required, especially in the handling of the hard woods, but notwithstanding this he has never had hernia. For a year and a half he has been employed in a cash-carrier factory, where his work is much lighter. He knows of nothing peculiar in his family history except that his father died of consumption. His height is five feet and three inches. His weight has varied but little from one hundred and five pounds since he attained to manhood. His general appearance is fairly healthy; his carriage is erect and firm, and his movements are quick and nervous. His figure is not muscular, and, though spare, is well formed except that his abdomen is full for a person of his general build, and, as he says, has always been so. His complexion is light, and his hair has been white ever since the age of seventeen. He has been near-sighted for many years, has always been nervous, and has had only one testicle from birth. His general health has always been good, and he had kept steadily at work until the forenoon of January 15, 1877, when, on account of a sudden attack of pain shooting from the lower part of his back directly forward through his abdomen, and accompanied by vomiting, he was obliged to give up his work, and go to bed. The pain increased so that on the following day Drs. Savory and Fisk were summoned. They found the patient suffering from pain in a tumor, which, from its form, size, and situation led them to think that it was a distended bladder. The catheter was readily passed, but it withdrew only a few drops of limpid urine. Aspiration was then resorted to, which resulted in the extraction of about two quarts of milky fluid, with entire relief to the patient. After the aspiration the tumor collapsed to a level with the surface of the abdomen, and in a day or two the patient was about his work apparently as well as ever. Throughout this attack there was no febrile action, no symptoms pointing to any organ, and no affection of the general system except nervous excitement from pain and fear of the operation, and some slight weakness for a day or two. The evacuations, both of the bladder and rectum, were normal. An experience like that just narrated was repeated on March 21 and October 3, 1877, and July 28, 1878, respectively, except that every recurrence of the tumor was preceded by an exacerbation of pain lasting for about three days, while the quantity of fluid diminished so that by the last aspiration scarcely twenty ounces were withdrawn. I was present on this occasion, and

[1] Read before the Massachusetts Medical Society, June 11, 1884, and recommended for publication by the Society.

can confirm the account of the case as given by the attending physicians. Some months after this the patient noticed a partial refilling of the tumor, and a subsequent retrocession thereof. The aggregate amount of fluid aspirated was about five quarts. After the first aspiration up to a year and a half ago he was subject to a dull ache in the lower part of the back, which was easily converted into a severe pain, shooting forward to the site of the tumor above described, by long walks or riding. This pain was also brought on when having a desire to go to stool he did not satisfy that desire at once. He had at times also some pain in the act of micturition. During the period just mentioned vomiting occurred at various intervals. The matter vomited consisted in the main of the same milky-looking fluid which was taken from the abdomen. When the vomitus was profuse general weakness followed for a few days. To these facts the patient, his wife and daughter testify with the greatest confidence. The patient has always had an aversion to milk, and has never used it except sparingly in coffee. He dislikes fat also.

These are the only peculiarities observed in his diet. From the time of the first to the last aspiration the vomiting was less frequent and the milky vomitus less abundant than afterward, when these symptoms had increased to such a degree that the daughter called the attention of her physician to the fact. He asked her to bring to him a specimen of the vomitus if it should appear again, but this request was never granted. The pain and vomiting had been growing less marked up to a year ago last March, when his last attack of vomiting took place while he was at work. This attack was accompanied by a loose discharge from the bowels, in which, as well as in the vomitus, the milky fluid, as he says, reappeared. Ever since this time he has been well in every way.

A specimen of the fluid withdrawn by the first aspiration was brought to me a few hours after its extraction. Its general appearance was that of milk. After standing a few hours it exhibited a soft and generally diffused coagulum. Although some of the fluid remained in my office for a week in a temperature which ranged from 60° F. to 68° F., there were no signs of decomposition. It was odorless, and its taste was mawkish. The reaction was alkaline, and the specific gravity was 1018. Ether extracted from it largely a clear, yellow fluid, in which, on the addition of nitric acid, an albuminoid precipitate was thrown down. Under the microscope were seen large quantities of molecular granules, fat globules, occasional crystals of cholesterine and granular corpuscles of different sizes, in some of which nuclei were revealed on the addition of acetic acid.

A portion of the fluid was sent to Professor Edes, of Boston, who replied as follows: —

"January 19, 1877. I received your very interesting specimen yesterday. It is, as you suppose, an emulsion containing very finely divided fat, like chyle, and granular corpuscles of various sizes and shapes, and fat globules, single and aggregated. Dr. Fitz found a little cholesterine. I found no cells, except those mentioned, to indicate in any way its source. Chemically ether extracts a large amount of fat, bright yellow in color. It contains also a large amount of albuminous substance which precipitates with nitric acid, but also, after being boiled with alkali, with acetic acid, which would assimilate it more closely to caseine. I was unable to get a trace of urea or anything like urinary pigment. There is also no urinary smell."

Professor Wood, of the Harvard Medical School, thus writes in allusion, as I think, to some oral observations which he had previously made on some of the fluid which had been taken from this patient: —

"December 7, 1878. I find nothing additional in my notes. The fluid was milky in appearance, and on being shaken with ether was rendered nearly clear. This clear fluid contained a large amount of albumen. The ether left, on evaporation, a large amount of fat. The microscope showed oil globules and lymph corpuscles in large numbers."

Unfortunately the fluid which was withdrawn by the last aspiration, and was sent to Professor Wood for a quantitative analysis, did not reach him till it was too old for examination.

In searching for precedents to the foregoing case I am mainly indebted to Professor Busey, of Washington, D. C., who has written two volumes, one entitled Congenital Occlusion and Dilatation of Lymph Channels, and the other, Narrowing, Occlusion, and Dilatation of Lymph Channels — Acquired Forms. A digest of the latter treatise, with some additions and modifications, may be found in the American edition of Holmes's System of Surgery.

Georgevic, in Langenbeck's *Archiv für Chirurgie*, vol. xii., p. 641, has written an article on lymphorrhœa and lymphangioma, and has illustrated his subject by a number of cases.

In Virchow's *Archiv für Pathol. Anat.*, vol. lxiv., No. 2, Dr. Weichselbaum, of Vienna, makes the discovery of a chylangioma cavernosum in the mesentery of the upper ileum the text for a summary of some contributions which had been made by different writers to the knowledge of lymphatic and lacteal pathology. There are also reports of cases relating to this subject scattered through various medical journals, but on the whole its literature is meagre.

In Professor Busey's work on the acquired forms of lymphatic disease is found the following classification: First, anomalies and lesions of the thoracic duct; secondly, rupture of the lacteals and receptaculum chyli; thirdly, chylous effusions into serous cavities. The vices of formation are mere curiosities of the dissecting room. It is stated, first, that diseases of the texture of the thoracic duct are usually the result of infection through the smaller lymph channels; secondly, that diseases of the lymphatic apparatus show a tendency to degenerative processes which have an enfeebling and wasting effect on the general system. It is evident, therefore, that we must look further than Professor Busey's first heading for analogies.

In an essay on dropsy by Donald Monroe, London, 1865, are found the following cases: (1.) In the body of a man who died after a large quantity of chylous liquor had been let out of his thorax was discovered, about the third or fourth vertebra, an orifice from which the chylous matter flowed as from a fountain. When the lower part of the thoracic duct was blown into the air came out at the above-mentioned orifice. (2.) A girl made too great an effort to raise a burden, and became hydropic soon after. Being frequently tapped there always issued from the puncture chylous matter. (3.) Hydrops lactea in a boy two years of age, which, after his death, was found to have been caused by a large number of indurated tumors which

compressed the thoracic duct, and had been the cause of a rupture of some of the lacteals.

Percival, in his Essays Medical, vol. i., London, 1788, reports the case of a girl who had ascites, and was anasarcous. Four quarts of a milky fluid were withdrawn at the first tapping. After the second tapping she recovered her appetite and strength. Percival suggests that she probably ruptured some lacteal by unusual exercise after a full meal.

Quincke, in the *Deutsches Archiv für klin. Med.*, vol. xvi., p. 121, reports a case of effusion of chyle into the right pleura from a ruptured chyle-vessel in a man who had been run over by a wagon.

The *Gazette Medicale de Strasbourg* (see translation in *Jour. Amer. Med. Assoc.*, August 4, 1883) describes a case of abdominal dropsy in which there had been eight tappings in four months, and each time four gallons of milky fluid were withdrawn, which Professor Rechlinghausen decided to be chyle from rupture of lacteals of the intestines or mesentery.

Dr. Mastin, in a subject affected with chylocele (see *Amer. Med. Weekly*, Louisville, Ky., vol. ii.), found the patulous mouths of three or four lymph vessels which discharged the fluid that filled the cavity of the tunica vaginalis.

From the preceding summary and from sources elsewhere studied we find that effusions of chylous fluid have taken place in various parts of the body, and that ruptures of the lacteals have been either seen or diagnosticated, but that from an anatomical stand-point a distinction must be made between deposits of true chyle and what, for want of a better term, we may call chyloid deposits. Two classes of cases illustrate this point of distinction: First, milky deposits in parts near the lacteals, for example, the abdomen and thorax; secondly, similar deposits in parts remote from the lacteals, for example, the labia majora, thigh, and ankles. The anatomical difficulty of remote deposits is explained as follows: —

Roberts maintains that the secreting structures in these cases are anatomically related to the lacteal and lymphatic tissues, which, in consequence of their hypertrophic development, have acquired the property and function of the cells lining the lacteal ducts and glands. Petters offers the theory that the chyle-like fluid arises from the fatty degeneration of the endothelium and other form elements, and in the decomposition of protein substances, which processes are brought about by the stagnation of lymph. Fetzer ascribes the phenomenon to the absorption of the surrounding adipose tissue by the lymphatics.

A comparison of the chemical and microscopic analyses made in our own case and in other cases of chylous effusion, the proximity of the tumor to the chylous centres, the suddenness of its first appearance, and the locality of the pain, suggest the idea that the fluid obtained from our patient was chyle from ruptured lacteals, and that this rupture may have been due to a strain in the abdominal region, possibly on vessels already distended; for, although there is no history of any special wrench at this time, it is notorious that the patient's work had been altogether too heavy for him.

In only two instances do we find mention made of the aseptic character of the chylous fluid, namely, Quincke's case, above quoted, in which the fluid extracted by ether remained fourteen days without any change in looks or smell, and Dr. Weaver's case, reported in *Med., Surg., and Pharm. Repository*, August 1814, in which the milky fluid was kept for several weeks without any appearance of decomposition.

The symptom of chylous vomiting finds a single precedent in the *New England Journal of Med. and Surg.*, vol. xii., p. 4, in which we read the following record: "Dr. Sprague was called to see a man who, while on duty as a sailor, being previously in good health, had been suddenly seized with a severe pain in his stomach and bowels and across the lumbar region, accompanied with the puking of a great quantity of chyle looking like frothy milk. He was pulseless, deathly cold, and pale. The fluid was discharged without effort. The quantity was variously estimated, by some as high as one gallon."

As to the symptom of chylous discharge from the bowels, we have only the testimony of the patient himself, but it seems not improbable if we admit the simultaneous occurrence of chylous vomiting. There is no history of repeated loose discharges, as was the case in the diarrhœa chylosa of the old authors.

Perhaps the most remarkable features of our case are, first, the apparently perfect recovery after so long a continuance of chylous phenomena; secondly, the repeated drain of chyle from the system without any appreciable loss of flesh or strength. But perhaps the drain was not large enough to produce these effects. All other cases that we have examined where the loss of chyle or lymph has been abundant have been attended with marked prostration. By abundant loss we mean the repeated removal of quarts, for example, the case of Recklinghausen, above described, and that reported by Saviard, in which, from July 2, 1669, to March 4, 1670, paracentesis was performed twenty-two times, and 289 French pints of chylous fluid, in the aggregate, were withdrawn.

But into whatever speculations we may be led concerning causes and symptoms in the absence of that best of all diagnosticians, a post-mortem examination, we may safely decide that what we have to deal with here is not malignant or organic disease, but more probably a mechanical lesion.

In conclusion the case is submitted to the profession with the hope that it may be a stimulus to farther investigations in the department of pathology which it illustrates.

NOTES OF TWO AUTOPSIES.[1]

BY S. D. PRESBREY, M. D., OF TAUNTON,
Medical Examiner.

I. Early in the morning of Wednesday, April 18, 1883, I was summoned by the police to visit East Taunton to investigate a sudden death, which the neighborhood had already dignified by the title of the "Squawbetty murder case." The dead body of a woman about fifty-five years of age had been found in a small house in "Bottle Row" (suggestive name), where, during the night previous, there had been a disturbance, and every indication of a drunken carousal. The house is a small one, having three rooms on the principal floor, a front, a middle, and a rear room. The front and rear rooms open from the middle room, and admission to the house is to the middle room through a small porch, which contains the kitchen

[1] Read at the annual meeting of the Massachusetts Medico-Legal Society, June 10, 1884.

sink, over which is a window, the sink and window being opposite the outer door.

This window and sink with its contents were stained with blood, much of which was in fine sprays as if caused by jets from a bleeding artery. The middle room contained many blood-stains of the same character upon the floor and walls, and even upon the articles of crockery on the table. On the floor, near the middle of the room, was a pool of blood. In the rear room was a bed, upon which lay an old man, his head resting upon a blood-saturated pillow, his hair and face covered with blood, and a large pool of blood was on the floor, under the head of the bed.

This man was living, but very weak from loss of blood, which had occurred from a cut in the forehead that had evidently divided a quite large branch of the temporal artery. The hæmorrhage had stopped, but the old man, feeble and bewildered, was unable to give a very clear explanation of his condition. The main idea with him was that he had interfered to prevent some one from being injured, and had himself got hit, he thought with a chair.

In the front room were a bed, a table, a stove, a lounge, and a few chairs. On the floor, in front of the lounge, was the dead body of the woman whose death was to be explained. She was dressed in her ordinary clothes. The body was prone. The face was inclined to the right, and rested in an iron wash basin containing, by estimate, six ounces of bloody water; the basin being slightly tipped by the weight of the head held this small quantity of water in such a way that the mouth and nostrils of the woman were completely covered by the fluid. The right leg was extended, the left flexed, the body resting upon the left knee and chest. The left arm was bent under the body; the right was extended by the side. On raising the body a little bloody water bubbled from the mouth and nose. A large bloody stain on the floor extended to the tipped edge of the basin; near the body on the floor were more marks of arterial bleeding, and on the table there was a cloth saturated with blood. There lay a pillow on the lounge with one blood-stain upon it. A pool of blood on the floor, near the head of the lounge, a bloody smooch on the wall paper near by, and a piece of blood-stained soap on the stove complete the sanguinary picture. An empty pocket-book was found on the floor, near the lounge.

The body was taken in charge by an undertaker, and conveyed to his rooms, while the proper steps were taken to prepare for an autopsy, which was made at three P. M. on the same day, with the assistance of Drs. Bassett and Galligan, of Taunton.

The record of autopsy was as follows:—

The body was that of a woman aged fifty-five to sixty years. Cadaveric rigidity was strongly marked. The skin was smooth. There was a slight abrasion one inch long on the right side of the forehead. There was a slight swelling on the right side of the head. Both of these latter, on incision, showed some ecchymosis. No other marks of violence was found. The nostrils and mouth were blood-stained. The tongue rested against the teeth.

The spinal cord was normal. The brain was normal. The sinuses and veins of the head contained rather more than the usual quantity of blood.

The mucous coat of the trachea was reddened and covered with a bloody, bubbling fluid. There was a bloody stain in the œsophagus.

The chest was quite filled by the lungs and heart. The large vessels, except the aorta, were filled with dark fluid blood. The heart and pericardium were normal. The right heart contained fluid blood. The lungs were healthy but dark in color and engorged. The liver was dark, and both liver and spleen were full of dark blood. Some bloody, bubbling matter was found in the stomach. The intestines were dark in color. The kidneys, uterus, and other abdominal organs were normal.

Diagnosis. Death by drowning.

As the body had been found in a house where it was known that there had been a drunken riot during the night it hardly seemed prudent to certify that the drowning had been purely accidental.

The public had become impressed with the idea that there had been a murder, and already two men, sons of the deceased, were under arrest. In consideration of these facts it was thought best to report the case for inquest as one of drowning, probably accidental, but possibly homicidal, that the facts and circumstances might be fully investigated.

The report of the inquest is as follows:—

The body of E. H. was found on the morning of the 18th instant lying dead in her own house, on the floor, near a lounge, with her face partly immersed in a basin of bloody water. The autopsy and other evidence in the case clearly show that her death was caused by drowning. There were no marks of violence upon her or wounds from which blood had flowed. The probability is that she fell from the lounge into the position in which she was found. That she was intoxicated may, perhaps, be inferred from the fact that a sober woman would not be likely to lie still and drown in a basin of water. The blood in the basin and about the house is accounted for by a drunken fight, which had taken place during the night between her two sons and one Flynn. At the time of her death the sons had probably left the house, and Flynn was asleep.

W. H. FOX, *Justice.*

April 20, 1883.

II. The second case is one of infanticide.

On the afternoon of Sunday, May 18, 1884, I was notified by the police that the body of an infant had been found floating in Taunton River. The body was at once removed to my stable, where it was kept carbolized till ten A. M. the following day, when, the proper legal formalities having been complied with, the autopsy was made, of which the following is the record:—

The body was that of a female infant. Weight, six pounds. Length, twenty-one inches. Umbilicus nearly in the middle of its length. Putrefaction advanced. Abdomen green. Head very soft; hair absent. Skin upon limbs hanging in shreds. Umbilical cord, three inches in length, cut but not tied. No ulceration of umbilicus. Incised wound in the front of the neck two and one half inches long, extending back to the spine, and dividing trachea, œsophagus, cervical veins of right side, and cervical veins and arteries of the left side. Incision marked by two serrations on the left side of the neck. Just above the left end of the cut a piece of skin of the size of a ten-cent piece had been smoothly removed. A slight superficial wound below and behind the left ear. Brain softened to a thick, pinkish fluid.

Thorax well filled by lungs and heart. Surface of lungs red and decidedly "marbled;" occasional bubbles on the surface from putrefaction. Lungs crepitate and spongy; edges rounded; a little bubbling, bloody fluid could be squeezed from cut surfaces. Contents of thorax, as a whole, floated high in water, and every portion of the divided lungs floated even after having been thoroughly squeezed.

Heart and large vessels normal and entirely empty. Ductus arteriosus patulous.

Liver dark in color and very soft.

Stomach contained a little grumous material, but no milk curds. Large intestine full of meconium.

The autopsy appears to justify the following conclusions: —

(1.) That the body is that of a full-time fœtus.

(2.) That the child lived and breathed.

(3.) That the child probably did not live more than twenty-four hours.

(4.) That the cause of death was hæmorrhage, possibly in part from the umbilical cord, but principally from the wound in the neck.

(5.) That the child has probably been dead at least two weeks.

Finding by W. H. Fox, Justice, May 22, 1884: —

"On the 18th of this month the body of a new-born infant, wrapped in a woman's skirt, was found floating in Taunton River, about a mile below Weir Bridge. The progress of decomposition indicated that it had been in the water perhaps twenty days. A deep gash across the throat showed that its short life had been abruptly terminated by the hand of violence. There is no evidence as to the author of this revolting crime."

RECENT PROGRESS IN GYNECOLOGY.

BY F. H. DAVENPORT, M. D.

SKENE'S DUCTS.

KLEMWAECHTER[1] refers to the two ducts opening on either side of the female urethra, which were first described by Skene in 1880, and later independently by Kocks in 1882. Skene considered them as the openings of ducts of glands, Kocks as the remains of the ducts of Gärtner. The author found the ducts present, but in two cadavers could not find gland structure at the end of the ducts; he therefore considers that they are not identical with the glandulæ vestibularis minores of Luschka, nor with the lacunæ in the neighborhood of the orifice of the urethra described by Henle.

The author saw a case of a young woman, twenty-three years of age, unmarried, who had suffered for three years from pruritus vulvæ which had resisted all treatment. As a result of the scratching the patient had become addicted to masturbation. Under chloroform the hymen was divided right and left, and the vulva cauterized with the hot iron. As a result the itching was much lessened and confined to the vicinity of the urethra. On pressure he found that pus exuded from the canals in question. He therefore injected tincture of iodine several times, and the result was a complete cure. The author thought the affection of the canals the primary one.

[1] Prag. med. Wochen., viii., 9, 1883.

DOUBLE UTERUS WITH DOUBLE VAGINA.

Dr. Dirner[2] describes the following interesting case: A woman, twenty-seven years old, began to menstruate at fourteen, regularly, but profusely, and with pain. She was married at seventeen, and had had no trouble until six months before consulting Dr. Dirner, when she noticed that urine escaped after every coitus. Examination showed that intercourse had been carried on per urethram, and that she had two vaginal orifices, so small that they would just admit a catheter. The physician who was at that time consulted enlarged the left opening somewhat, and advised that it should be used in coition. Pregnancy followed, but she miscarried at the fourth month.

A careful examination by the author showed a dilated urethra, easily allowing the finger to pass, hanging from the lower side of which was a small tumor the size of an almond, which was plainly the prolapsed urethral mucous membrane. The ostium vaginæ was apparently closed, as is seen in atresia hymenalis, but on either side under the labiæ minores two small openings were found. These were the entrances to the two distinct vaginæ, each with its uterus, the left rather larger than the right. These were connected, as was clearly made out by combined examination by bladder and rectum, by a membrane the width of two fingers.

An operation was performed to unite the two vaginæ and narrow the opening in the urethra, a detailed description of which is given. This was successful, and the patient, after one more miscarriage, became pregnant again, and was delivered of a living child from the right uterus. Both before and after birth the left uterus could be distinctly felt, somewhat enlarged and softened, and during the after-pains, when the right uterus contracted firmly, the smaller left uterus could be felt to grow smaller and become harder.

PARTIAL EXTIRPATION OF THE CANCEROUS UTERUS.

Dr. Ely Van de Warker[3] advocates in this paper a method for the partial extirpation of the cancerous uterus by the use of more powerful caustics than have heretofore been used. After destroying all the cancerous tissue possible with scissors, knife, or curette, he packs the resulting cavity with iron cotton. This is removed on the second day, and the uterus repacked with cotton soaked in a 100 per cent. solution of chloride of zinc. Should the walls be very thin at any point a weaker solution of ℥v. to ℥i. of water is used over this part. The resulting pain is easily controlled by morphia. In from two to five days the zinc cotton may be removed, and in from five to ten days the slough comes away. This is often a quarter of an inch thick, and in some cases seems to be virtually the whole of the uterus. Cicatrization is completed in from two to four weeks. Several cases are reported which show how much may be gained even in those apparently hopeless cases where the knife cannot reach all the diseased tissue.

CHANGES IN THE UTERINE MUCOUS MEMBRANE DURING MENSTRUATION.

Wyder[4] discusses this subject in an interesting article, and as a result of microscopic examinations of the uterus in cases of persons who have died suddenly during menstruation, and of examination of the uterine

[2] Arch. f. Gyn., Band xxii., Heft 3, 1884.
[3] Am. Jour. of Obstet., March, 1884.
[4] Zeitsch. für Geb. und. Gyn., Band ix., Heft 1, 1883.

secretion of blood and mucus carefully aspirated on different days of menstruation (in one case removing portions of the mucous membrane with the curette), has come to the following conclusions: —

(1.) During menstruation a portion of the superficial layer of the mucosa is destroyed, the extent varying in different cases from a very thin layer to an almost complete destruction. These portions thrown off are sometimes found intact, and sometimes in a condition of degeneration, and as detritus.

(2.) The shedding is a consequence of the menstrual flow, not of primary fatty degeneration. The latter is rather a result of the loosening and destruction of the tissues by the hæmorrhage.

(3.) The superficial and middle layers of the mucous membrane keep their small-cell character, and have no resemblance to the decidua of pregnancy, while in the deepest layers we find a cell infiltration of the interglandular substance, which is evidently intended to serve to replace the destroyed tissue.

(4.) The regeneration of the lining epithelium proceeds as well from the glandular epithelium as from the small islands of the superficial layer which remain.

STUDIES OF THE UTERINE MUCOUS MEMBRANE.

Dr. Düvelius[1] in this article considers three questions in connection with curetting the uterus: (1) the possibility of making a correct diagnosis from the portions of uterine mucous membrane removed by the curette; (2) the possibility of so completely destroying the diseased mucous membrane by the curette that one can be safe from a return of the disease; (3) the possibility of a normal pregnancy occurring after this procedure.

To determine the first point the curette was used on twenty-two uteri from women who had died of other affections than uterine. This was done before post-mortem changes could have begun, and as carefully as if on the living subject. The uteri were then examined, and with the exception of the first three cases, in which the curetting was not so carefully done, the muscular layer was laid bare over the whole extent of the uterine cavity. There were, however, in all cases small isolated portions of the mucous membrane remaining attached, and the ends of the glands which dipped down into the muscular tissue were found. Enough, however, could be obtained to make a diagnosis easy. In nine cases of examination during life the diagnosis was made with the microscope, and confirmed by an examination of the uterus, which was in each case removed. Two were of carcinoma, two of malignant adenoma, one of sarcoma, and four of endometritis adenomatosa. The author considers the first point as sufficiently proven.

As regards the second point, namely, the return of the disease, while its possibility cannot of course be denied, yet the writer considers that energetic curetting, especially if followed by appropriate treatment at the time by caustics, etc., very much diminishes the probability.

Two points throw light upon the third question, that of possible conception. First, examination of uteri which have been the subject of thorough curetting, and have subsequently been removed, show microscopically a complete regeneration of the mucous membrane and an absence of cicatrices; *a priori*, therefore, we would expect the possibility of conception.

[1] Zeit. für Geb. und. Gyn., Band x., Heft 1, 1884.

Second, numerous examples of its occurring in persons who have been the subject of this operative procedure are on record. In the five years from 1879 to 1883 the reports of sixty such cases were found by the author.

IGNIPUNCTURE OF THE CERVIX UTERI.

L. Prochownick[2] refers to the almost complete abandonment of the use of the hot iron and galvanocautery, and says that in most minor affections of the cervix uteri the knife, scissors, and the suture have rightly taken the place of the incandescent instruments. He, however, thinks that with reference to the wedge-shaped incision, and amputation of the vaginal portion, there is some doubt. In his experience he has had failures, and he has found a good many patients who were unable to devote the necessary time and means for the more elaborate operation. He has therefore devised the following method of dispensary treatment: Two or three times between each period four ignipunctures, two in the anterior and two in the posterior lip, are made with the pointed galvano-cautery, or the Pacquelin, the latter when greater depth is required. The direction of the punctures is centrifugal or centripetal, according to the nature of the case; the former for indurated hypertrophy without profuse catarrh or ulcerations, the latter for opposite conditions.

The patient should rest half an hour after the operation, and then may be allowed to attend to her ordinary occupations. There is some swelling of the cervix for a few days, and the granulating depressions heal in between two and three weeks. In general five or six operations suffice, and the result is cessation of cervical catarrh, healing of eroded surfaces, and a marked diminution in the size of the cervix. The author has in forty cases not had a relapse, and has observed no unpleasant consequences.

THE RELATIONS OF OVULATION AND MENSTRUATION.

Lawson Tait[3] in this article reviews again the evidence in this much-disputed question, and again expresses his well-known views of the complete independence of the two functions. He first refers to the statement that menstruation in woman is analogous to rut in the lower animals, and claims that this is not so, on the grounds that, first, both the congestion and periodicity are too faulty (?) in the lower animals to constitute an analogy; second, that while impregnation occurs in the lower animals only during the œstrus, "in the human subject (quoting Dr. Farre), whatever may be possible during menstruation, yet essentially the intervals of the menstrual act are the times of fertility in women;" third, that our limited experience goes to prove that so far from the sexual desires being strongest at the menstrual period the reverse is the case.

The author then asks the question, whether it is true that the so-called ovarian excitement, alleged to arrive at the ripening of a follicle, has anything to do with the process of menstruation. The facts which he considers to have bearing on this point are, that in newborn infants and children there are sometimes Graafian vesicles or ovisacs, in which at the fourteenth year ova may be detected, showing, therefore, the possibility, "*if rupture should occur*" (the italics are ours), of impregnation taking place without menstruation; that these

[2] Am. Jour. of Obs., May, 1884.

[3] Med. Times and Gazette, May 10, 1884.

vesicles "all through life discharge by circular-shaped capillary-sized openings in the peritoneal coat, the presence of the catamenia being thus no indispensable prerequisite to their rupture;" that Graafian follicles of some size are found for many years after the menopause; that as there is no analogy between menstruation in woman and the rut, the innumerable experiments on animals have been not only useless but misleading; that impregnation "occurs often in the absence of the catamenia, as in the amenorrhœa of lactation and other conditions; and, lastly, that in the experience of ovariotomists, "in many cases in which both ovaries have been removed, these organs have been found so thoroughly diseased as to preclude the idea that they could possibly have performed the functions of ovulation normally, if at all, and yet the regularity of menstruation has suffered no interruption, and also that after the removal of both ovaries, and even tubes, menstruation has occurred regularly."

The author next relates his own experience from the opportunities abdominal surgery has given him of observing the ovaries during life. He has always found that during menstruation the tube is fastened on the ovary, whether there be a ripe follicle at the point of adhesion or not; that both tubes were generally fastened to their respective ovaries, though in one ovary there may have been no appearance of a ripe ovisac; that he has very frequently seen a ripe ovisac on the point of bursting, or just burst, when the patient was midway between two menstrual periods; and, finally, that in two cases he has removed ovaries with the tubes fastened on them during menstruation, in none of which were there any ovisacs approaching ripeness.

The paper closes with short records of forty-nine cases of abdominal section in which the condition of the ovaries was noted, with the following results: There were nine cases where it was evident that menstruation and ovulation were concurrent; fifteen cases of negative proof against the ovulation theory of menstruation; and twenty-five affording positive evidence against the theory. (This is an ingenious paper, and presents a long array of arguments in support of the theory advanced by the author, but we cannot but feel that many of them are faulty, and that the true significance of the facts is often perverted. It is, however, of value as expressing the opinion of one who has made a close study of the ovaries for many years, and as a contribution to this much-vexed question. No satisfactory theory of the connection of these two functions, ovulation and menstruation, has yet been given, but we do not feel that Lawson Tait has by any means satisfactorily demonstrated his theory to be the correct one. — REP.)

A CONTRIBUTION TO THE PATHOLOGY OF HYDRO- AND PYO-SALPINX.

Dr. J. Kingston Fowler[1] gives a very interesting series of fifteen cases of hydro- and pyo-salpinx met with in the post-mortem room of the Middlesex Hospital in the course of the last three years. Clinical details are omitted, but at the head of each case an abstract has been placed of the changes found in the various organs, followed by a fuller description of the condition of the parts more immediately concerned. The cases as given are very interesting, but we have space only for the conclusions. "It is very probable," the author says, "that many cases of peritonitis which have been regarded as idiopathic, as secondary to abscess of the ovary or pelvic cellulitis, have been really due to rupture of a Fallopian tube, distended with pus, into the peritoneal cavity." In eight of the fifteen cases, all pyo-salpinx, the state of the tubes was the immediate cause of death. Of the eleven cases of pyo-salpinx death was due to peritonitis in seven, and in one case each to septicæmia, amyloid disease, cancer of the uterus, and scurvy. "There can be no doubt," the writer says, "that any inflammatory condition of the uterine mucous membrane, however induced, it may be by extension of a vaginitis, or some affection of the os or cervix uteri, by a retroflexion, by the presence of a fibroid tumor or polypus, or as a result of prolapse or malignant disease, may spread to the Fallopian tubes, and ultimately establish the condition of pyo-salpinx." He has noticed that in many cases there is an induration close to the uterine end of the tube, the lumen of which is at that point entirely obliterated. In three cases such obliteration seems to have been due to the presence of fibroids.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

C. H. WILLIAMS, M. D., SECRETARY.

APRIL 7, 1884.

DR. A. N. BLODGETT read a paper on

SUBSCAPULAR ABSCESS.

DR. HOOPER mentioned two cases in infants. In the first case the scapula stood out at an angle with the chest wall like a wing, and the pus worked its way into the pleural sac; in the other an operation was done to allow the pus to escape and the child recovered.

DR. F. MINOT had seen two cases. The first looked like an effusion into the abdominal cavity, but an exploratory incision showed a collection of pus under the skin and over the abdominal fascia. The second was a young lady, twenty-two years old, whose health had always been good, noticed some pain in the upper part of the back, below the left shoulder, which was increased on motion of the arm. On examination a tumor was found just outside the edge of the scapula. It lay rather deeply, somewhat towards the axilla, at about the edge of the trapezius muscle. It was about as large as an egg, round, smooth, quite movable, and slightly tender. It was thought to be a fatty tumor, and an incision was made into the tissues over it extending through some fibres of the trapezius, when a sudden jet of pus showed the supposed tumor to be an abscess. An ounce of healthy pus was discharged through the enlarged opening. The abscess lay partly upon the lower portion of the scapula. The wound was brought together with sutures, a bit of rag being left in the lower part for drainage, and was completely healed in about ten days.

DR. A. T. CABOT then showed the specimens from

A CASE OF DOUBLE OVARIOTOMY.

The patient, a woman fifty years of age, ceased menstruating five years ago. Four years ago she began to

be troubled with frequency of micturition and occasional slight pains in the left side of the abdomen. She noticed at this time a swelling in the left hypogastrium. When seen by Dr. Cabot the tumor occupied the whole abdomen, reaching nearly to the ensiform cartilage.

The operation was done ten days ago. A cyst of the left ovary, with a long, twisted pedicle and a number of long adhesions, was readily emptied and removed. It was then seen that there was also a multilocular cyst of the right ovary. This latter tumor had been so held down by the superincumbent larger cyst that it had not been able to rise out of the pelvis and form a pedicle for itself, but was firmly imbedded behind the uterus and was fastened by a wide base to the right broad ligament, between the layers of which some of the cysts had grown.

Examination showed that Douglas's cul-de-sac was occupied by one large cyst which was so immovably fixed that it seemed as if it must be adherent somewhere, though no adhesions could be reached. After trying in vain to separate the tumor from the broad ligament the overlying cysts were drawn to one side and the large cyst deep in the pelvis punctured. It was found to be not adherent, but simply wedged in the pelvis. When empty it allowed the whole mass to be lifted out, and the tumor was then readily separated from the broad ligament. The hæmorrhage from the wounded surface in the pelvis was considerable, but was finally controlled.

The patient's temperature rose to 101° F. the night after the operation, but never reached that point again. Except a moderate abdominal soreness for the first twenty-four hours she suffered no pain, and her recovery was uninterrupted. The stitches were all taken out on the day of the report, and the wound found to be healed by first intention.

The cysts, with their fluid contents, weighed eighteen pounds.

The inner walls of several of the cysts were occupied by an extensive papillomatous growth with here and there yellow patches of fatty degeneration. The fluid, which resembled thick pea soup in appearance, was filled with large granular cells and granular matter.

Dr. C. M. Green showed a specimen of human ovum with a definite history as to age, of six to seven weeks. The villi of the chorion had begun to atrophy, leaving about two thirds free from villi.

Dr. Charles H. Williams reported

AN ALLOPLASTIC OPERATION.

The patient, a man twenty-two years old, received a severe burn of the left side of the face when a child. The lower lid has since then been everted, the ectropion involving the outer two thirds of the lid and exposing a strip of conjunctiva about five millimetres wide. An operation was done at the infirmary after Wolfe's method, by transplanting a piece of skin without pedicle from the arm.

The edges of both lids were first freshened, a cut was then made about five millimetres from the edge of the lower lid and parallel with it, and the cicatricial tissue which bound the skin to the underlying bone was dissected up so that the edges of the lids could be brought together by three sutures. A piece of skin about four by two centimetres was then taken from the anterior surface of the upper arm and inserted in the opening made in the lid. The subcutaneous tissue was trimmed off from the under surface of the flap before its connection with the skin was entirely severed, and the flap was then at once removed to its new place and secured by ten fine sutures, great care being taken to bring the edges well together and to avoid any rolling in of the epithelial surfaces.

While the sutures were being applied the flap was kept warm by a succession of sponges dipped in hot water, and finally the parts were thickly sprinkled with iodoform, a thick pad of absorbent cotton was laid on, and the whole secured by a long flannel roller bandage. This dressing was allowed to remain untouched for six days; at the end of that time the flap was found to be somewhat whiter in color than the surrounding skin and to be anæsthetic, otherwise the parts looked well and were in good position. The sutures were removed from the edges of the flap at this time, but those in the edges of the lids were allowed to remain one day longer, when they were also removed and the lids were found to be firmly united for three quarters of their length. At the inner angle a free space was left, through which the discharge from the conjunctival surfaces found exit.

Ten days after the operation a small blister was seen near the centre of the graft and another near the lower edge; the epithelial surface was slightly raised, and there seemed to be a slight serous effusion underneath. The blister at the lower edge continued to increase in size for several days, and the loose epithelium was finally peeled off with the forceps from about one tenth of the graft, leaving an uneven red surface underneath. A fresh layer of epithelium soon spread over this surface from the edges of the wound, and this process was repeated until the whole of the epithelial layer of the graft had exfoliated and had been replaced by new. In the mean time a considerable shrinkage had gone on in the size of the flap, and from measuring 3.25 by 1.5 centimetres one week after the operation it had come to a strip three centimetres long by half a centimetre wide. About two months after the operation the tissue uniting the lids was divided. At first there was very little ectropion remaining, but after two weeks the swelling of the conjunctiva increased and the eversion became fixed, though less than half as great as before. A second operation was therefore done to correct the remaining deformity by removing a wedge-shaped piece of the conjunctiva and underlying tissue. A cut was made along the inner surface of the lower lid, three millimetres from its free edge and parallel with it. The knife was carried parallel to the tarsus to the depth of more than half a centimetre. A second cut was now made, parallel with the first, but holding the knife at such an angle that the two cuts would come together at the depth of half a centimetre. In this way a wedge-shaped piece of tissue was removed having sides about one half a centimetre broad and of a length equal to the everted portion of the eyelid. Two deep sutures, each with two needles, were then passed through the skin a little below the eyelashes, and going backward through the subconjunctival tissue were brought out on the cheek 1.5 centimetres below the point of entrance, and the lower ends being tied the cut edges of the conjunctiva were brought into apposition and the eversion was reduced.

After four days these sutures were removed, there had been no suppuration along their track, the wound had healed, and the ectropion had disappeared.

PROCEEDINGS OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

H. C. HAVEN, M. D., SECRETARY.

APRIL 26, 1884. DR. J. C. WHITE presiding. Eighty-five members present.

REPORTS OF COMMITTEES.

The committee appointed at the stated meeting October 27, 1883, on the restoration of the National Board of Health, reported any action to be at present inexpedient.

The Committee on Social Meetings reported a balance on hand of $163.73.

The treasurer reported an expenditure during the past year of $432.99, and a balance in the treasury of $231.13.

DR. A. DAY presented a paper entitled Medical Delusions.[1]

The officers were elected for the ensuing year according to the nominations reported in the JOURNAL, April 17th.

PRIMARY CANCER OF BLADDER.

DR. WHITNEY showed a specimen of primary cancer of the bladder, situated in the right posterior wall, and involving the opening of the right ureter. This was dilated, as well as the pelvis of the kidney, which was in a condition of hydronephrosis. The left ureter was normal in size, and the kidney showed fatty degeneration of the convoluted tubes. The lumbar glands on the right side were diseased, and the liver was filled with nodules of new growth.

The microscopic examination showed the disease to be of the flat-celled variety of cancer.

The specimen came from an old man who had had hæmaturia for eight months, but no pain. Gradual loss of strength and death.

DOUBLE OVARIOTOMY.

DR. A. T. CABOT showed the specimens from a case of ovariotomy, which were interesting from the fact that a parovarian cyst was associated with a cystic condition of both ovaries.

The patient, twenty-four years of age, had noticed a gradual increase of size during the past four years. The catamenia had not been noticeably irregular. When seen the whole abdomen was occupied by a fluctuating swelling, which to aspiration yielded a fluid similar to that shown.

Ovariotomy was performed, and both ovaries being found to be cystic were removed with the broad ligament cyst, which was of considerable size, and contained twenty-five pounds of fluid. The patient made a good recovery.

Dr. Cabot pointed out how easily the parovarian cyst would have shelled out of the broad ligament had not the disease of the ovary required its removal also. One ovary was about the size of half a lemon, the other as big as a large orange; both were thoroughly cystic (multilocular). The parovarian cyst was a great unilocular sac, thin walled, and the specimen of fluid from it was as clear as water, and contained almost no albumen, but abundant chlorides.

DR. J. W. ELLIOT remarked that he was very much interested in Dr. Cabot's specimen; that the presence or pressure of an ovarian tumor seemed to favor the occurrence of cysts in the other ovary. Dr. Elliot farther remarked that he had recently removed an ovarian tumor which had so grown down into the broad ligament that he found it necessary to enucleate it from under the peritonæum; that in this case the other ovary was so much enlarged that it was supposed to be cystic, and was accordingly removed, but upon examination no cyst was found. The patient made a good recovery. Dr. Elliot also referred to another case, operated on one month ago, where he found a dermoid cyst, which contained a large quantity of hair, bone, and skin. He had intended to exhibit the specimen at this meeting, but had, unfortunately, forgotten to bring it. This dermoid cyst had been of rapid growth, only nine months. The only symptom had been constant uterine hæmorrhage. The tumor had been supposed to be a uterine fibroid. The patient made a quick recovery. The temperature was not above 99.8° F.

COLD BATHS IN THE TREATMENT OF PNEUMONIA.

A recent contribution to the subject of this method of treating pneumonia is summarized from *Vratch*, by the *London Medical Record* (July 15th), as follows: — The author, Dr. M. K. Kiseleff, states that in 1880 forty-four patients with pneumonia were admitted to the Grozuyi Military Hospital; twenty-three of them were treated by cold baths, at the temperature of 28° R. to 26° R., with gradual cooling to 16° R. or 12° R. The baths were made daily, between four and six o'clock P. M., and lasted from ten to fifteen minutes. Before and after each bath the patients received from three to six ounces of sherry or *vodka* (*eau de vie*). The results were as follows: (1.) The mortality amongst the patients treated by baths was lower than amongst those left without baths (respectively 17.7 per cent. and 57.1 per cent.) (2.) The curves of morning and evening temperatures, the pulse and respiration, did not present any great differences; but while in the patients left without baths a high temperature lasted all day long, in those treated by baths it fell 1.5° C. to 3° C. for four or five hours daily. Further, the pulse after each bath decreased from ten to twenty beats, and pain disappeared. The respiration remained unchanged. (3.) Crisis in bath-cases occurred apparently earlier (in three cases on the third day, in two on the fourth, in two on the fifth, in two on the seventh, in two on the eighth, in five on the sixth, in one on the ninth, in four on the tenth, in two on the thirteenth; while in the cases left without baths crisis frequently occurred on the ninth day). (4.) Cold baths had no influence on the frequency of complications, but the latter ran a more favorable course. (5.) Recovery proceeded more rapidly (nineteen patients treated by baths recovered between the tenth and twenty-seventh day since the appearance of first symptoms). In 1881 and 1882, Dr. Kiseleff treated other forty-nine patients by cold baths. Only three (6.12 per cent.) died. Crisis occurred not later than on the eleventh day, most frequently on the sixth and ninth. The patients left the hospital in three or four weeks, being quite strong and sound. The author's general conclusion is, that cold baths present a powerful therapeutic agent in the treatment of pneumonia. He points also to such important advantages of baths as disappearance or diminution of pain, absence of delirium, advent of quiet sleep, etc.

Medical and Surgical Journal.

THURSDAY, AUGUST 14, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

THE RESCUE OF LIEUTENANT GREELY AND HIS SURVIVING COMRADES.

WE have just seen an effective illustration of the adaptability of the human constitution to all climates and temperatures, as well as its power to endure extreme privation, in the rescue from starvation and death of Lieutenant Greely and the remnants of his party, — a rescue the more remarkable that it was accomplished amid such dangers and brought deliverance out of such miseries, — and in the thrilling story of the hardships which this party underwent from the time that they abandoned Fort Conger, August 9, 1883, till they were found off Cape Sabine in Smith's Sound by Lieutenant Schley, July 4, 1884. During more than nine months the party lived on the scant allowance of food brought with them, and a small quantity found in *caches* left by other expeditions. When this was exhausted, — and the last regular rations were issued about the first of May, — they had to live on boiled seal-skin strips from their clothing, lichens, and shrimps. It is not a wonder that on such fare any died, it is a wonder that any survived.

A point of interest in connection with this history, is that at the time when Greely and his men left Fort Conger they were all well and in good spirits, and there is every probability that, could they have reached Littleton Island where there was abundant food stored away for them, they would all have been living at this day. For two years, then, these twenty-four American adventurers, born and nurtured in a temperate climate, and with constitutions not above the average in robustness (their leader had been somewhat shattered by malaria) withstood with impunity and even with physical advantage, in a latitude of 82°, the rigors of a climate where, according to Hartwig, "the average temperature of the winter generally ranges from — 20° to — 30°, or even lower, and for a great part of the year is able to convert mercury into a solid body."

The conditions whereby man is able to bear the excessively low temperature of an Arctic winter are stated in a very few words; a thick fur clothing; a hut, small and low, where the warmth of a fire, or simply of a train-oil lamp, is husbanded in a narrow space, and a copious supply of animal food, of flesh and fat. With the descent of the thermometer the internal processes of combustion are increased, for the air, condensed by the cold, furnishes more oxygen to the lungs; the circulatory system and the muscles experience a marked augmentation in tonicity; the appetite and digestion are stimulated to an extraordinary degree.

"The mysterious compensations," says Kane, "by which we adapt ourselves to climate are more striking here than in the tropics. In the Polar zone the assault is immediate and sudden, and unlike the insidious fatality of hot climates, produces its results rapidly. It requires hardly a single winter to tell who are the heat making and acclimatized men. Peterson, for instance, who has resided for two years at Upernavik, seldom enters a room with a fire. Another of our party, George Riley, with a vigorous constitution, established habits of free exposure, and active cheerful temperament, has so inured himself to the cold that he sleeps on our sledge journeys without a blanket or any other covering than his walking suit, while the outside temperature is thirty degrees below zero."

In connection with the means necessary to fortify the human system against extreme cold nothing is of more importance than suitable alimentation, and had Greely and his men been reduced in mid-winter to the extremes to which they were brought later in the year, when it was warmer, soups made of lichens and seal-skin boots could hardly have saved one of them. Indeed, the only nutritious substance available to them in that bleak and barren waste seems to have been shrimps, the most diminutive of decapods, and the supply even of these was quite insufficient.

The problem of the sustenance of human life in a condition of fair nutrition and vigor within the Arctic Circle seems to have been now decided in the affirmative, and we shall probably soon see the hazardous experiments of Lieutenant Greely and party repeated on a grander scale, and with greater precautions for safety. It must, however, be borne in mind that only the naturally robust and hardy are fitted to withstand the polar cold. The physician cannot safely recommend his cardiac, phthisical, or dyspeptic patients to try the tonic, bracing effect of a winter at Fort Conger, albeit exceptional cases might be benefited. Captain Ross has judiciously treated this question of constitution. "What good," says he, "to give fur garments to him who is incapable of engendering bodily heat?" He regards as certain that men who are endowed "with a great appetite and splendid digestion" are more fitted than others to produce animal heat. The "sanguine temperament is also a favorable condition, especially when it is accompanied with an energetic character, which habitually keeps up confidence, cheerfulness, and hope in the midst of the most trying circumstances."[1]

The "confidence, cheerfulness, and hope" are probably no less requisite to success in these arduous experiences than are the other qualities, personal and objective. In fact, the physiologist and the therapeutist recognize them as everywhere the foundation principles of a healthy and enduring vitality.

[1] Ross, Narrative of a Second Voyage, page 165. (Quoted by Longet, Traité de Physiologie, t. ii., p. 543.)

A NEW ANTIPYRETIC.

DR. PAUL GUTTMAN has lately introduced to the Medical Society of Berlin a new alkaloid, a derivative of quinoline, which bears a striking resemblance to quinine, while being more antipyretic than the latter. This medicament, which has been called *antipyrine* by Professor Filehne, has been obtained by Professor Knorr in the laboratory by way of synthesis. Antipyrine presents itself under the form of a white crystalline powder, very soluble in water, rather tasteless, easily tolerated by the stomach, especially when taken with wine or aromatics.

According to Professor Filehne this substance, exhibited in doses of two grammes every hour till six grammes are taken, is said to give constant antithermal results even when the fever is very high. The antipyretic action lasts from seven to nine hours, sometimes very much longer, and the pulse becomes less frequent. May has tried this new remedy in the hospital of Cologne in the treatment of typhoid fever, and is enthusiastic in its praises. In his practice it has proved superior to quinine. Rank expresses himself similarly as the result of fifty observations in the hospital at Stuttgart. Guttman's trials are, however, the most numerous, and they seem to have been the most thorough. His cases, reports of which he has made to the Society, number 120. Twelve of these were cases of typhoid fever, eight of pneumonia, three of scarlet fever, four of intermittent fever, etc. All these affections were complicated by a high fever. Given in the doses before mentioned (ʒss. per hour for three doses) antipyrine was observed always to cause a marked fall in the temperature, which lasted five or six hours and even longer. In the first hour which follows the administration of the medicine the temperature falls half a degree, and the decline goes on increasing during the second hour, and attains its maximum during the third. As the temperature lowers perspiration appears. No secondary unpleasant effects have been noticed, unless occasional vomiting be excepted. The medicament is very soluble in warm water, a half gramme of the latter dissolving one gramme of the alkaloid. In this form it may be administered hypodermically, and so introduced it exercises a speedy, safe, and efficient action. The only febrile disease in which antipyrine seemed to be without effect was intermittent fever.

When given in antifebrile doses this medicine has always been found to be free from the inconveniences which attend sulphate of quinine in large doses, such as headache and intoxication. It would seem from Dr. Guttman's experience to be of about half the strength of quinine, that is, to get the full antipyretic effect which you would derive from two grammes of quinine you must give four grammes of the other.

The cost of antipyrine is about two thirds of that of quinine. Dr. Guttman has expectations that, now that it can be produced synthetically from relatively inexpensive materials, there will soon be a considerable reduction in its price.

In the discussion which followed the reading of Dr. Guttman's paper Dr. Tillmans related his experience with the new medicament in the Charity Hospital. In general his observations confirm those of Guttman. He finds that patients enfeebled by chronic affections (suppurations, tuberculosis, etc.) are very susceptible to the action of antipyrine even in small doses. Antipyrine is on the whole admirably supported. It may be given for months together without the least harm resulting. Tillmans has, in fact, given it uninterruptedly for months to tuberculous patients, and has kept the temperature within very nearly the normal bounds.

In pneumonia it is necessary to give large doses, for otherwise you cannot control the temperature. In very bad cases of this disease Tillmans has brought down the febrile heat from 40.1° C. to 37.8° C. in six hours, by giving during this time seven grammes of antipyrine, and this reduction of temperature has lasted twelve hours.

In one case of typhoid fever Tillmans gave antipyrine from the beginning to the end of the malady, and kept the temperature almost within the normal limits.

Guttman has invariably found when giving antipyrine that when the fever again rises after the effect of the medicine passes off the elevation of temperature is not attended with a chill, as is the case when kairine is given. The same fact has been confirmed by Falkenshein.

A trial of the medicine at the Boston City Hospital during the last three months confirms, as far as the experiments go, these observations and conclusions. Three successive hourly doses of thirty grains cause not unfrequently a fall in temperature of four to six degrees, the subsequent maximum not being attained for eight to twelve hours, and then being less than the initial temperature. No inconveniences have been experienced.

On the whole the profession seems to have in antipyrine a febrifuge of no little promise. It is to be regretted, however, that its originator should not have felt it unworthy of German science to cover the discovery with a patent.

MEDICAL NOTES.

— In a recent number of the *Lancet* Alexander Harkin states that a painful area normally exists upon percussion over the fourth and fifth dorsal vertebræ. This pain is described as "peculiar; some compare it to an electric shock diffused over the chest and arms, others liken it to the tingling sensation caused by a knock upon the ulnar nerve at the bend of the elbow, and all declare that it is of a most disagreeable nature." He has examined a large number of children and adults, male and female, and finds it constantly present.

— In 1835 Toulon lost 1656 inhabitants from cholera; in 1849, 751; in 1854, 1135; in 1865, 1331. The inhabitants remember that on former occasions

the disease made its appearance in a mild, insidious form, and suddenly rose to an alarming degree of intensity.

— At a recent meeting of the Berlin Medical Society photographs were shown by Professor Virchow of the gigantic plane tree in the Island of Cos, under the shade of which Hippocrates is said by tradition to have held medical consultations. The tree stands in the market-place of the town of Cos, on the east side of the island, and the branches, which spread over nearly the whole of the market-place, are supported by marble pillars.

— An ingenious model was exhibited before the Ophthalmological Society of the United Kingdom at its recent meeting, by Mr. J. Streatfeild, for demonstrating ophthalmic operations as well as other points of instruction to a class. The model was made on a scale exactly ten times that of the actual eye, and the models of the eye instruments were on the same scale excepting that the handles of the instruments had been altered and shortened. The apparatus, which consisted of the front of an eye, permitted of rotation in every direction, and the eye could be fixed in any desired position. The sclerotic and the eyelids were constructed of white felt. The cornea was made of stout glass of the right curvature. The iris was imitated in thin sheet India-rubber, with a round hole for the pupil. The cataractous lens was made of xylonite. The internal and external rectus muscles of the eye were represented by pieces of linen bandage. With this apparatus could be represented the *modus operandi* of peripheral section of the cornea, of iridectomy, of extraction of cataract, and of squint operations. The anterior chamber could only be entered for iridectomy, cataract extraction, etc., in the usual place, at the sclerotico-corneal junction. Here at any part of the upper half circumference the knife, forceps, pricker, or curette could be entered between the felt sclerotic and the glass cornea, which gave way for their admission, and resumed its natural position when the instrument was withdrawn. The sheet India-rubber, of which this imitation iris was made, could be seized with the (model) iris forceps at any part, drawn out of the eye, more or less, and so much cut off as might be desired in the demonstration. Mr. Streatfeild illustrated his remarks by performing a cataract extraction on the model.

— In a town in Normandy lives an aged lady named Marie Durant, much visited, who is believed to be one hundred and twenty-three years and a few weeks old, but who, when asked, with true feminine instinct declares she does not know. For ninety-six years she has been a widow, and during her lifetime four kings have ruled, the stars of two emperors have risen and set, and three republics have been established. She lives exclusively on vegetable diet, but is always ready for a *petit verre* of cognac, and says she would have died but for frequent doses of it during a recent illness. Her skin is brown and wrinkled, and all the flesh seems to have disappeared from under it, though there are still small veins of color on her withered cheek.

— *A propos* of guess-work, the *London Medical Times* remarks (July 12th): Every great scientific theory has commenced in a guess, or, to speak of it more respectfully, a flash of genius or inspiration. That theories, medical or otherwise, are merely convenient guesses at truth, to be employed as working hypotheses, liable to modification or rejection as further facts are brought to light, essentially forms the distinction between a scientific and an unscientific guess. Every diagnosis is at first more or less of a guess. The original guess may be raised to a high condition of probability by the course of disease, by alterations of temperature, the development of physical signs, the appearance of a rash, etc., but frequently these may be misleading, and absolute certainty can be obtained only by post-mortem examination. A riddle may have numerous answers besides the right one. In disease a consideration of the same data may lead to a dozen different conclusions. It would be painfully interesting if the commentaries written by the candidates at such an examination as that for the London M. D. were published collectively. It is notorious that the diagnoses arrived at from the same facts vary considerably, and much ingenuity must be expended in endeavoring forcibly to twist these stubborn articles into a pillar of strength, in which, it may be, every particle is proclaiming its protest against misuse. In the examinations of our daily life, however, guess-work must always play an important part, its value depending largely on the degree of flexibility exhibited by the medical man. He who starts with a wrong diagnosis, and refuses to modify his originally expressed opinion, in view of fresh facts, will more certainly lose the confidence of his patients than he who frankly admits his error. Guess-work, invaluable as an aid when scientifically used, only becomes a direct evil when it leads to an uncompromising dogmatism.

— Pelizaeus examined 2,403 children between the ages of six and thirteen, with respect to the presence or absence of the patella reflex. Out of all these children there was only one boy in whom he was never able to obtain the patella reflex, in a few others in whom it was not present at the first examination it was always found on subsequent trials. The boy in whom it was absent was apparently in perfect health. These results are very different from those obtained by Eulenburg and Berger, who found an absence of patella reflex in 4.8 and 1.56 per cent. of the children examined. — *Archiv für Psychatrie*, etc., Bd. xiv., Hft. 2.

— Somnambulism is one of the subjects to be taken up by the committee for the collective investigation of disease in England.

— Dr. E. L. Keyes [1] gives the result of his experiments in a number of cases of gonorrhœa with some of the methods of treatment which have recently been recommended, especially those by hot water and by corrosive sublimate. His temporary conclusions are as follows: (1.) A mild corrosive sublimate solution irritates the urethral mucous membrane more than it

[1] Journal of Cutaneous and Venereal Diseases, March, 1884.

seems to irritate an open wound. (2.) It appears that an abortive treatment of gonorrhœa is yet to be discovered. (3.) The hot water treatment of gonorrhœa is unreliable.

— Mr. Lawson Tait reports in the *Lancet* (July 12th) two cases of remarkably high temperature taken by several observers and verified by himself, four independent thermometers agreeing in the record. In one case of a woman with chronic ovaritis a full temperature record is presented covering a period of two weeks; enormous variations are shown, from 99° upwards. Twice the temperature was 106°, once 107° twice 108°, three times 109°, six times 110°, and four times 111°. Another woman from whom both ovaries had been removed for cystoma showed a temperature at one time, verified like that in the other case by different observers and instruments, of 111°. There were no other untoward symptoms, and she made a good recovery.

— Under the new regulations for Government Life Insurance, says the *Lancet*, a novel experiment is being tried, the result of which will be watched with interest. Insurances for sums not exceeding twenty-five pounds are now granted at any post-office savings bank without any medical examination. If, however, an insurant should die before the second annual premium becomes payable, the amount of the first premium, and no more, will be paid to his representative; should the insurant die after the payment of the second, but before the third premium becomes due, the representatives will be paid only half the amount of the policy. After the payment of the third premium the policy is entitled to full benefit. It is nevertheless provided that in case of death within two years of an insurant who has not been medically examined, if it can be proved to the satisfaction of the Postmaster-General that the death was caused by accident, the full amount of the policy will be paid. Persons proposing to insure for sums not exceeding twenty-five pounds, and preferring that their policy should have the full benefit of insurance at once, can undergo a medical examination by payment of a fee of half a crown to the medical examiner. The rules do not explain the nature of the arrangement by which the fee for medical examination to be paid by the insurant is to be supplemented. The new system by which insurances may be granted through post-office savings banks affords great facilities for industrial insurance combined with absolute security, which, it may be hoped, will commend the system to the working classes. In view of recent abuses which have come to light in the insurance of children, it is worthy of observation that no insurances will be granted upon the lives of children under eight years of age, and the amount is limited to five pounds for children aged between eight and fourteen years.

— The experiments which M. Pasteur is reported thus far to have made with hydrophobia are said to be an unbroken success. Fifty-seven dogs have been the subjects of investigation. Of these nineteen were rabid, and by these thirty-eight healthy animals were bitten under uniform conditions. Of the thirty-eight, one-half the number had been previously inoculated or "vaccinated with attenuated virus; the other half had not. The latter, without a single exception, died with unequivocal signs of rabies, whereas the nineteen others remain as well as ever. They will be watched for a year by veterinary surgeons to see whether the inoculation holds good permanently or only temporarily.

Correspondence.

"NEPOTISM AT THE MASSACHUSETTS GENERAL HOSPITAL."

MR. EDITOR, — I believe the readers of the JOURNAL appreciate its sense of humor and are grateful for its attempts to soften the asperities of life. Perhaps they have never been treated to anything more amusing than the "Statement in Regard to the Charge of Nepotism at the Massachusetts General Hospital." It reminds one of the ludicrous attempts of an inebriated person to assure his friends that he is not intoxicated; or better still, of an individual charged by common rumor with intoxication, who takes pains to prove to the world that he is not dead drunk. The Massachusetts General Hospital is not yet old enough to appoint all its house pupils from the comparatively few families of its trustees and medical staff, and must fill up its quota from outsiders. Eight appointments in ten years of gentlemen who bear the well-known names of members of the staff is by no means a bad showing, but a candid statement in regard to the matter should not be confined to those degrees of relationship which are betrayed by identity of names.

It is often said that the appointments are influenced by favoritism, a word that includes nepotism and much more, and the "statement" expressly says that the appointments are not prizes to the best scholars and that the examinations are not intended to be tests of knowledge. Other qualifications are sought, and what can be more natural than that the nominating body should see those qualifications best marked in the sons of their friends and their friends' friends. The consequence naturally is that students rely upon other means than scholarship to gain the coveted positions. Occasionally a man forces his way in, so to speak, by superior scholarship, provided he takes care to exhibit also those other qualifications mentioned in the statement and it happens to be an "off year" for favorites. The names alone in any list of internes does not cover the ground. To fully understand the matter it would be necessary to recall the history of each year; to learn who was not appointed and the various reasons which influenced the individual members of the nominating and appointing bodies in making the several appointments.

But it is hardest of all to understand why any excuse or statement is necessary in regard to the matter. No hospital management would consent to have its house officers appointed by lot, and there are but two other ways — as the result of an examination, which *is* a test of knowledge, or by the arbitrary choice of the appointees. The first method is the most feasible in hospitals maintained at public expense; a private institution may adopt either method, and, though it is pleasing to the friends of a hospital to feel that its

favors are bestowed in such a manner as to encourage true scholarship, there is much to be said in behalf of the favoritism method. Why should not the wishes of a man who helps financially to sustain the institution be regarded? Why should not a physician or surgeon be influenced by the wishes of his dearest friend or most profitable patient? The question is not intended even to suggest improper influence, but simply to say that the gentlemen referred to are subject to like influences as other men, and they cannot help trusting the children of their friends, who have grown up around them, rather than the strange young men who may be equally good, but whom they do not know.

Certainly this much must be said, internes appointed by vote are much more likely to be amenable to control than those who have compelled their appointment by virtue of a superior examination. A certain feeling of pride is natural to a man who has come off victorious in a contest, either mental or physical, with his fellows, and the winner of a hospital examination is probably a little more ready to criticise and instruct his visiting physician or surgeon than the man who owes his place to favor; and nobody supposes that the hospital suffers from the present method. Favoritism also gives a chance to those individuals who have not the ability or the industry to pass an examination, but do possess the faculty for learning by experience, and make, in the end, some of our finest practitioners.

Each method has its advantages, and each its disadvantages; neither can escape criticism, but neither needs to justify itself by showing that it is not the other.

X. Y. Z.

THE PLASTER-POSTERIOR SPLINT.

KEENE, N. H., *August* 6, 1884.

MR. EDITOR: *Sir*, — My attention has been called to the foot-note appended to a very interesting article by Dr. George W. Gay in the *Boston Medical and Surgical Journal* of July 24th, in which is said: "A practical demonstration of the plaster-posterior splint was made before the Society by Dr. R. A. Kingman, of Boston, who perfected and brought it into use in this vicinity while he was house surgeon at the City Hospital in 1881. The efficiency and popularity of the splint are largely due to Dr. Kingman's skill and ingenuity."

Will you kindly allow me to object to the idea of any great amount of ingenuity being shown by my friend Dr. Kingman in regard to this splint, and I feel sure he will agree with me in the objection.

Nearly five months before Dr. Kingman entered the City Hospital, Dr. George Goodhue, of New York, told me of this splint as having been successfully used in the New York hospitals, and from that time on Drs. Cutter, Bullard, Squires, and I used it, as needed, continuously and successfully, and the splint so minutely described by Dr. Gay is to all intents and purposes identical with the first one applied, February 22, 1881, by Dr. Cutter and myself, under the supervision of Dr. Goodhue; and the hospital records describe the use of this antero-posterior splint by the house surgeons many times before July 4, 1881, on which day Dr. Kingman entered the hospital as surgical interne. The point I wish to make is that, in view of these facts, it seems hardly fair to ascribe to Dr. Kingman's skill and ingenuity the "efficiency and popularity of this splint."

Very truly yours,

GEORGE H. BRIDGMAN, M. D.

Miscellany.

THE DIAGNOSIS OF MITRAL CONSTRICTION.

SIMPLE mitral constriction, remarks a writer in the *Medical Times and Gazette* January 5, 1884, is of far more frequent occurrence than is generally allowed, and its diagnosis probably presents greater difficulties than any other serious lesion of the valves on the left side of the heart. We exclude from consideration cases which are complicated by regurgitation, because the latter, when advanced enough to produce grave symptoms, is easily detected; and the presence of constriction as well in such cases is not of great practical importance. But when, as not rarely occurs, the question is whether stenosis of the mitral orifice be present, and the cause of serious symptoms, or whether the heart be healthy, and the distress and danger due to other conditions, accurate diagnosis becomes a matter of the utmost moment. In a typical case the observer feels a thrill at the apex preceding the impulse of the heart; he hears at the base a clear second sound over the aortic valves, an exaggerated one to the left of the sternum, and at the apex a rolling presystolic murmur, gradually increasing in intensity and leading up to a short and sharp first sound, which is not succeeded by any appreciable second sound. The diagnosis of mitral stenosis under such circumstances admits of little doubt. But in a second series of cases both murmur and thrill may be absent, and the heart's action regular, and the difficulty of detecting the disease then becomes great. The most striking auscultatory phenomena are accentuation of the second sound at the base to the left of the sternum, and, what is of much greater importance, a peculiar hesitation in the production of the first sound, a kind of "hanging fire," which is easier for the experienced auscultator to appreciate than to describe. Whatever be its origin, whether it be a faint sound caused by the blood passing through the constricted orifice into the ventricle, and so practically a murmur, or be due to a slowly beginning, though suddenly ending, ventricular contraction, it is a phenomenon which at once strikes the ear and suggests the nature of the disease. In these and all other cases of suspected constriction of the mitral orifice, the detection, if possible, of increase in size of the left auricle and right side of the heart yields valuable corroborative evidence. There is a third class of cases, in which there may be no murmur, no thrill, no hesitating first sound, but extreme irregularity of cardiac action, the beats being very frequent and very irregular both in rhythm and in force; so much so that a great many of them produce no pulsation at the wrist. In some cases as many as half the beats of the heart are not felt in the radial artery, so that the pulse there may be moderate in frequency, although the cardiac contractions succeed each other with extreme rapidity. Similar phenomena may likewise be observed in cases of simple dilatation of the heart with degeneration of its walls, such as occurs, for example, in chronic bronchitis and emphysema; but then the patient is usually past middle life. If grave cardiac symptoms be found in a comparatively young person, and if auscultation only reveal extreme irregularity in the heart's action, the presence of mitral stenosis ought to be at once suspected. The administration of digitalis in such cases not only often removes the patient's distress, and produces regularity and normal frequency of the heart's

beats, but also facilitates diagnosis. For when the heart's action gets slow and regular a presystolic murmur frequently makes its appearance. Finally, there are cases of considerable mitral constriction which produce no sufficiently well-marked morbid phenomena to enable the observer to detect the presence of heart disease. But the pathologist not infrequently meets with these narrowed orifices in the post-mortem room in patients who have died from other diseases. The reflection is then forced upon him, how extreme some pathological conditions require to be before they come within range of our present powers of diagnosis.

LATE MARRIAGES.

DR. F. STEINMANN, of St. Petersburg, has recently published, says the *Lancet*, the results of his researches into the question of how far childbirth and lying-in are unfavorably affected by the primipara being old when she first becomes a mother. The estimate of the time when a primipara is called old varies between twenty-five (Fasbender) and thirty-five years (Mangiagalli), but Dr. Steinmann accepts that which most authorities have adopted, namely, thirty years. From twelve years' statistics of the St. Petersburg Maternity Hospital, during which time there were 28,279 deliveries, it appears that there were in that period 645 old primiparæ. Of this number a fraction over 69 per cent. were thirty to thirty-four; 26.2 per cent., thirty-five to thirty-nine; and 4.2 per cent., forty years and over; one of these was fifty-two years old. In 1875, when the general mortality was three and a half per cent., that of old primiparæ was nearly fourteen per cent.; and again, in 1881, when the general mortality was only one half per cent., that of the old primiparæ was eight per cent. A decidedly greater fœtal mortality when primiparity is late is also shown by the statistics collected by Dr. Steinmann, and, although the subject demands more attention from the profession than it has heretofore received, the facts adduced by him furnish strong reasons for objecting to late marriages.

SURGICAL TRIUMPHS AND OPERATIVE AUDACITIES.

MR. A. JACKSON, of Sheffield, England, at the completion of a quarter century of incumbency of the lectureship on surgery at the Sheffield School of Medicine, made an address on A Quarter of a Century's Surgery: Its Lessons, its Failures, its Disappointments, its Prophecies,[1] which is of value as presenting the view of one who is evidently a conservative as to what is of permanent value in the so-called advances of surgery in the past generation. We subjoin the following extracts: —

After premising that "the great commotion or progress — whichever view be taken of it" — of this period is largely due to two factors — anæsthetics and antiseptics — and granting the enormous value of the former in operation as well as in diagnosis, he goes on to say: "But while chloroform and antiseptics have had their advantages, have they done no harm? I think they have. What a terrible tale would abdominal sections tell, were they all recorded *accurately*, after the able method of Sir Spencer Wells! How often have they been done unsuccessfully! I am not alluding to ovariotomy, for that is one of the few successes of the last twenty-five years — a success founded upon a rock which neither the winds of fashion nor the fickleness of the English people will ever shake. I am alluding more particularly to the exploratory operations for the relief of internal strangulation; for the relief of pain; for caries of the spine; and also to those cases where portions of the stomach and intestines have been removed, gastrostomies performed, etc., etc. As Mr. Erichsen puts it, 'Will the surgery of our time record "surgical triumphs or operative audacities?"' May I substitute the word 'atrocities?'

"Far be it from me to say that these operations are wholly unjustifiable. I have sinned — in my opinion — many times. But is it not time to pause and consider whether they are justifiable; whether they are successful sufficiently often to continue them; and to try and perfect our diagnosis before we make this a permanent operation. Syme, fifty years ago, used the word gastrostomy, and condemned the operation; and I think we are bound to have stronger reasons than we have at present for running counter to the judgment of one of the greatest surgeons of the century.

"The St. Bartholomew Hospital Reports (1884) record twenty-one abdominal sections, with nineteen deaths, exclusive of ovariotomies. . . .

"With regard to the treatment of diseases of bones and joints, more particularly the hip, the knee, and the tarsal bones, are we where we were twenty years ago? With regard to the hip-joint and the tarsal bones I think we are. The recognized modes of treatment of the hip-joint have failed. I do not mean in every case, but in the majority. I think excision of the head of the femur has failed because enough bone has not been removed, and it has not been resorted to early enough; but so far as I know at present it is the only mode of treatment with any chance of success except in the early stages. Excision of tarsal bones or gouging them out may also be classed amongst our failures; and I would urge a more frequent resort to Syme's operation.

"Every department in surgery has been harassed and unsettled; no one knows better how much has been done in this way than the unfortunate man who has to lay down laws for the students in lecture; for in the very outset, with regard to the treatment and dressing of an incised wound, the treatment of a fracture, there are no rules, no laws; each man does that which is right in his own eyes, and there are almost as many different methods of treatment as there are clinical teachers.

"Each hospital has its own particular way of treating broken bones. We have the same miserable sequelæ, ankylosed joints, œdematous legs, pain, thickening, want of power, as formerly; and no one stops to think if anything can be done to prevent their occurrence.

"Oh, that several workhouse medical officers would write a book on the Sequelæ of Hospital Surgery. Such a book, with a hospital surgeon's account of his mistakes, would do more to advance surgery than the publication of so many successful cases. The treatment of empyema is now one of the burning questions of the day; and we find men advocating the removal of a portion of not one rib only, but of four or five; and we are asked to consider the propriety of draining

[1] Medical Press, July 9, 1884.

pulmonary vomicæ, and the removal of portions of lung. 'Are these surgical triumphs or operative audacities?' . . .

"In a deal that is now called new and brought forward as instances of progress, we are now only returning to the modes of treatment suggested and practiced in days gone by. The ligature of the sac for the radical cure of hernia was many years ago practiced by the elder Teale. Cystotomy for irritable bladder was introduced by Paget, of Leicester. The kidney was successfully removed twenty-five years ago; osteotomy twenty-four years ago.

"To sum up, I am inclined to think that, in future, we shall find surgery stepping in and dealing successfully with ruptured bladders, perforating ulcer of the stomach, and kidney diseases; but I do think we ought to make a stand against performing large operations on internal cancers until we know more about their laws of recurrence. I think we ought to watch with very great jealousy the results of our osteotomies, our abdominal sections, and drainage of pulmonary vomicæ. We ought to try to find out what is the best treatment for spinal disease and diseases of bones and joints in their early stages; to invent some more satisfactory way of treating fractures; and to publish more of our unsuccessful cases."

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 2, 1884.

Deaths reported 3364 (no report from Buffalo): under five years of age, 1800; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases), 1040, diarrhœal diseases 705, consumption 360, lung diseases 138, diphtheria and croup 77, whooping-cough 57, typhoid fever 57, malarial fevers 44, measles 38, scarlet fever 31, cerebro-spinal meningitis 15, erysipelas six, puerperal fever six, small-pox three, typhus fever one. From *whooping-cough*, New York 19, Boston 12, Brooklyn 10, Philadelphia five, Baltimore, District of Columbia, and Nashville two each, St. Louis, Cincinnati, Pittsburg, Milwaukee, and Providence one each. From *malarial fevers*, New Orleans 15, St. Louis 12, Brooklyn six, Baltimore five, New York four, Charleston and Chelsea one each. From *measles*, New York 18, Chicago seven, Philadelphia four, Brooklyn and Pittsburg three each, Boston, Cincinnati, and New Orleans one each. From *scarlet fever*, New York seven, Philadelphia six, Chicago and Boston four each, Cincinnati and New Haven two each, Brooklyn, Baltimore, Pittsburg, Providence, Lowell, and Cambridge one each. From *cerebro-spinal meningitis*, New York three, Philadelphia and Fall River two each, Chicago, Boston, Baltimore, St. Louis, Cincinnati, Nashville, Springfield, and Holyoke one each. From *erysipelas*, New York two, Chicago, Cincinnati, Milwaukee, and New Haven one each. From *puerperal fever*, Chicago three, Brooklyn, Boston, and St. Louis one each. From *small-pox*, New Orleans two, Philadelphia one. From *typhus fever*, New York one.

Cases reported: scarlet fever 42, diphtheria 22, typhoid fever nine, and measles four in Boston; scarlet fever 31, and diphtheria seven in Milwaukee.

In 106 cities and towns of Massachusetts, with an estimated population of 1,528,732 (estimated population of the State 1,955,104), the total death-rate for the week was 19.11 against 21.54 and 17.68 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 26th, the death-rate was 24.0. Deaths reported 4031: acute diseases of the respiratory organs (London) 177, diarrhœal diseases 838, whooping-cough 129, measles 117, scarlet fever 83, fever 36, diphtheria 29, small-pox (London 23, Liverpool and Sheffield one each) 25. The death-rates ranged from 14.0 in Bristol to 34.6 in Leicester; Birkenhead 16.6; Birmingham 20.7; Bradford 17.2; Leeds 27.3; Liverpool 27.1; London 26.1; Manchester 24.2; Nottingham 29.2; Sheffield 26.7. In Edinburgh 17.6; Glasgow 26; Dublin 21.9.

For the week ending July 19th, in the Swiss towns, there were 43 deaths from diarrhœal diseases, consumption 33, typhoid fever 20, lung diseases 14, diphtheria and croup three, scarlet fever one, erysipelas one. The death-rates were, at Geneva 25.5; Zurich 11.8; Basle 21.4; Berne 22.2.

The meteorological record for the week ending August 2d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date. July–August, 1884.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM AUGUST 2, 1884, TO AUGUST 8, 1884.

WOODWARD, Jos. J., major and surgeon. Sick leave of absence extended six months. Paragraph 9, S. O. 178, A. G. O., July 31, 1884.

GIBSON, J. R., major and surgeon. Granted leave of absence for one month and fifteen days. S. O. 36, headquarters Division of the Atlantic, August 4, 1884.

HEIZMANN, C. L., captain and assistant surgeon. Relieved from duty at Columbus Barracks, Ohio, and ordered for duty in Department of the East. Paragraph 2, S. O. 150, A. G. O., August 2, 1884.

MCCREERY, GEO., first lieutenant and assistant surgeon. Leave of absence extended two months. Paragraph 4, S. O. 180, A. G. O., August 2, 1884.

TAYLOR, A. W., first lieutenant and assistant surgeon. Ordered for temporary duty at Fort Riley, Kansas. Paragraph 1, S. O. 153, headquarters Department of the Missouri, July 29, 1884.

HOPKINS, W. E., first lieutenant and assistant surgeon. Granted one month's leave of absence, with permission to apply for one month's extension. Paragraph 1, S. O. 67, headquarters Department of Arizona, August 1, 1884.

BENHAM, R. B., first lieutenant and assistant surgeon. Assigned to duty at Fort Brown, Texas. Paragraph 1, S. O. 90, headquarters Department of Texas, July 19, 1884.

GANDY, C. M., first lieutenant and assistant surgeon. Granted leave of absence for one month, — to commence between August 15th and 30th, — provided he furnish medical attendance at Fort Brady, Mich., during his absence. Paragraph 5, S. O. 154, headquarters Department of East, July 30, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY DURING THE THREE WEEKS ENDING AUGUST 9, 1884.

HARMON, G. E. H., passed assistant surgeon. Ordered to temporary duty at Norfolk Navy Yard.

SAYRE, J. S., assistant surgeon. Ordered to U. S. S. Independence.

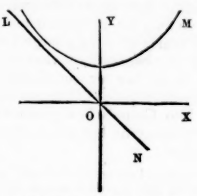
THE VALUE OF PROBABILITIES IN MEDICAL RESEARCH.

BY F. J. B. CORDEIRO, M. D.,
Assistant Surgeon U. S. Navy.

BY probability we understand the projection of the past into the future, — a process by which we avail ourselves of bygone experience. Or probability and experience are two ends of a connected series vanishing in one direction into the future, the other into the past. The end spanning the future we can liken to a bridge springing out into the air from a buttress, and this buttress is the past. The farther back the buttress extends the longer out can we build our bridge. The word "probably" occurs constantly throughout Medicine, and what word could occur more properly in one of the less exact sciences? It was latest in my ears when Dr. Warren, in determining whether or no a needle was in the foot of his patient, said, "Two halves of a needle were seen before the accident, afterwards only one. The probability would have been greater if a whole needle had been seen before the accident and a half afterwards." Such a case is easily dealt with by common sense, as we say. Not so simple is the following: Suppose the obturator artery arises from the epigastric once out of every two subjects in the female, and once out of every five in the male. Suppose that when so arising it goes to the inner side of the crural ring, in the proportion of one out of eleven subjects. Suppose it arises by two trunks, one of which is from the epigastric, in one out of seventy-two subjects. Suppose the above anomalies occur unilaterally four times to every time they occur bilaterally. What, then, is the danger of wounding the obturator artery in operating for crural hernia in a given case? The theory of probabilities gives us readily

For female,
$\text{Danger} = (\frac{1}{2} \cdot \frac{1}{11} + \frac{1}{72} \cdot \frac{1}{11})\ (\frac{1}{5} + \frac{4}{5}) = .0255.$
For male,
$\text{Danger} = (\frac{1}{5} \cdot \frac{1}{11} + \frac{1}{72} \cdot \frac{1}{11})\ (\frac{1}{5} + \frac{4}{5}) = .0106.$

That is, if the statistics are correct, the accident will happen 255 times out of every 10,000 females operated on, and to 106 males out of every 10,000.



If we measure a quantity a given number of times we shall have as many errors as we make measurements. These errors will vary in magnitude. If we make an infinite number of measurements we shall hit as often above as below the true value, and by as much, that is, for any number of errors of a given magnitude with a plus sign, we shall have as many of a like magnitude with a minus sign. In other words, if we were to measure an angle a very large number of times with the plainest kind of quadrant, we should get a more accurate result than from a few measurements by the most elaborate verniers and micrometers, provided the instrumental errors in each were equal. And we should get an absolutely accurate result from our imperfect instrument, provided we made an infinite number of observations. Thus, like Jason's horde sprung from the dragon's teeth, our errors annihilate each other.

Let x be an error, carrying with it its sign. We can formulate our law above $\Sigma x = o$. This is the law of the Arithmetic Mean. Let us integrate the expression $x_1 + x_2 + x_3 \ldots + x_n = o$. We have $\int \Sigma x\, dx = \frac{1}{2} \Sigma x^2 + C$.

It follows that Σx^2 is a minimum for $\Sigma x = o$. This is easily seen also by the following. If we shift our origin to a point x_o, the residuals of the measurements will be $x - x_o = x'$.

$\Sigma x'^2 = \Sigma x^2 - 2 \Sigma x x_o + n x_o^2$. But $\Sigma x = o \therefore \Sigma x'^2 = \Sigma x^2 + n x_o^2$. Hence $\Sigma x'^2$ is a minimum only when $\Sigma x'^2 = o$. This is the principle of Least Squares.

The function $\Sigma x'^2$ changes value with change of origin, according to the law

$$\Sigma x'^2 = y = C + n x^2,$$

that is, it shifts in the parabola $L\,M$, as per figure. The function $\Sigma x'$ shifts in the line $L\,N$.

It is important to bear in mind, as is easily seen by the simple proof above, that the law of the Arithmetic Mean and the principle of Least Squares are absolutely true only for an infinite number of observations. For a small number of observations their value is not great, but their accuracy and *applicability* increase rapidly as the observations increase.

Let us now consider if the proportions in which errors of different magnitudes occur is subject to law for an infinite number of observations. I give here Gauss's beautiful demonstration of this point.

Let $y = f(x)$ be the probability of the occurrence of the error x. The probabilities of various errors x_1, x_2, x_3, etc., then are $f(x_1), f(x_2), f(x_3)$, etc. The probability of the simultaneous occurrence of these errors is the product of their separate probabilities.

$$\text{Let } P = f(x_1), f(x_2), f(x_3), \text{ etc.} \qquad (1.)$$
$$\text{Then } \log P = \log f(x_1) + \log f(x_2) + \text{etc.} \qquad (2.)$$

Now the absolute values of x_1, x_2, x_3, etc., being unknown, we wish to determine the most probable system of values. Of all possible systems, that one is most probable which makes P a maximum. Differentiate (2),

$$\frac{d\,P}{P} = \frac{d\,f(x_1)}{f(x_1)} + \frac{d\,f(x_2)}{f(x_2)} + \text{etc.} \qquad (3.)$$

Let $d\,f(x) = \phi(x), f(x), dx$ where ϕ is some form of function. Substitute in (3) and equate to o.

$$\frac{d\,P}{P} = \phi(x_1)\,d\,x + \phi(x_2)\,d\,x + \text{etc.} = o. \qquad (4.)$$
$$\therefore \phi(x_1) + \phi(x_2) + \phi(x_3) + \text{etc.} = o.$$

But $x_1 + x_2 + x_3 + \text{etc.} = o$ by the principle of the Arithmetic Mean. Hence ϕ means simply multiplication by some constant k. Hence

$$\frac{d\,f(x_1)}{f(x_1)\,d\,x} = k\,x_1$$
$$\therefore \frac{d\,y_1}{y_1} = k\,x_1\,d\,x$$
$$\text{Or, generally, } \frac{d\,y}{y} = k\,x\,d\,x.$$

$$\text{Integrating, } \log y = \frac{k\,x_2}{2} + k^1$$

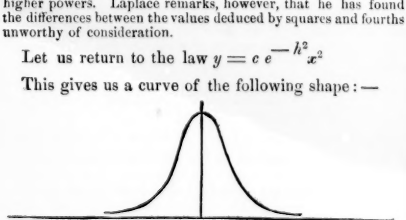
$$\therefore y = e^{\frac{k\,x^2}{2}} e^{k^1} = c\,e^{-h^2 x^2},$$

where $c = e^{k^1}$ and $\frac{k}{2} = -h^2$. We derive, then, the law of the probability of error, $y = c\,e^{-h^2 x^2}$ — a remarkable result. Let us understand that this law is absolutely true only for an infinite number of observations, though nearly true for a large number. With a small number of observations chance wanders as it pleases: there is no law or semblance of law; but gradually, as the observations increase, chaos begins to marshal itself into Gauss's law, given above. There exists, therefore, either no law at all or an approximation to Gauss's law.

The following historical digression will not be without interest. The impression has prevailed among many writers, past and present, that various laws of probabilities might exist under different circumstances. Merriman[1] says, with Laplace, that he is unaware that any one has yet proved the *a priori* probability of the Arithmetic Mean. I quote: "It is distinctly conceivable, and hence *a priori* possible, that in different classes of observations different laws of error might exist; therefore we ought not to expect that from merely theoretical considerations a single definite law of error should result."

Gauss, as long ago as 1809, seems to me to have had a comprehensive and just understanding of the whole subject. To him belongs the whole credit in this branch of probabilities. Laplace showed that for most accurate results the sum of the errors raised to the 2*n*th power should be used, the accuracy increasing with *n*. But the condition is intrinsically the same where the squares are taken. For the condition $x_1 + x_2 + x_3 +$ etc. $= o$ is equivalent to the condition $x_1^3 + x_2^3 + x_3^3 +$ etc. $= o$.

Integrating this last expression, we have



$$x_1^4 + x_2^4 + x_3^4 + \text{etc.} = k.$$

This must be a minimum when $x_1 + x_2 + x_3 +$ etc. $= o$. And so on for any power $2n$. Using the test that the fourth powers of our errors shall aggregate a minimum we shall have a smaller value for the error of our mean. For the function $\Sigma x'^4 = \Sigma (x - x_0)^4$, (where x_0 is the error of our mean) $= \Sigma x^4 + 6\,\Sigma x^2 x_0^2 + n\,x_0^4$. Therefore the function $\Sigma x'^4 = y$, shifts according to the law $n\,x_0^4 + 6\,C\,x_0^2 + C^1 = y$, as we shift our origin x_0.

The function $\Sigma x'^2$ shifts, as we have seen, according to the law $n\,x_0^2 + C = y$. Hence for a given value of the function y we shall get a smaller value of x_0 in the former law of variation than in the latter. And this applies with increasing force to higher powers. Laplace remarks, however, that he has found the differences between the values deduced by squares and fourths unworthy of consideration.

Let us return to the law $y = c\,e^{-h^2 x^2}$

This gives us a curve of the following shape: —

The probability that an error will fall within a certain limit x_0 is $2\,c \int_0^{x^0} e^{-h^2 x^2} dx$.

$e^{-h^2 x^2}$ can only be integrated by the aid of an infinite series. Between the limits o and ∞ it has been accurately integrated by Poisson.

$$\int_{-\infty}^{+\infty} c e^{-h^2 x^2}\,dx = \frac{c}{h}\sqrt{\pi}$$

[1] Method of Least Squares.

But this integral, representing the sum of all the probabilities, must equal unity. $\therefore c = \frac{h}{\sqrt{\pi}}$ h can be considered as a parameter of precision, for the probability of a given error is diminished as h increases. When h is 8. $y = o$, that is, the possibility of error is precluded. When $h = o$, $y = o$. This is a logical equation and means not that there is a probability of nothing, but that there is no probability, as in that case law is at an end.

The value of x corresponding to $h\,x = .4769$ — where the probability is $\frac{1}{2}$ — is called the probable error. It shows that an error is as liable to fall without as within its limit.

h, in terms of the errors, $= \sqrt{\frac{n+1}{2\,\Sigma x^2}}$.

Let r denote the probable error of a single observation. We saw that $h\,r = .4769$.

$\therefore r = .4769 \sqrt{\frac{2\,\Sigma x^2}{n+1}}$. Let r_0 denote the probable error of the Arithmetic Mean. We have $h_0 r_0 = .4769$, but $h_0 = \sqrt{n}\,h$ $\therefore r_0 = .4769 \sqrt{\frac{2\,\Sigma x^2}{n\,(n+1)}} =$ $.6745 \sqrt{\frac{\Sigma x^2}{n\,(n+1)}}$.

Likewise $r = .6745 \sqrt{\frac{\Sigma x^2}{n+1}}$.

Dienger[1] has calculated these formulæ differently.

According to him $r = .6745 \sqrt{\frac{\Sigma x^2}{n-1}}$.

$$r_0 = .6745 \sqrt{\frac{\Sigma x^2}{n\,(n-1)}}.$$

Practically, as there is no great difference between the formulæ, I shall use Dienger's, as they have become somewhat established. I do not think them so accurate as the others, however.

Let us now apply some of the foregoing work to Professor Bowditch's excellent tables on the growth of children. According to his measurements the average height of Boston schoolboys five years old is

For Americans . 41.74
For Irish . . . 41.59

These are founded on the following observations: —

Inches.	American.	Irish.
47	2	-
46	1	5
45	6	6
44	18	31
43	29	53
42	37	65
41	46	77
40	33	64
39	12	41
38	9	17
37	4	5
36	3	1
35	1	-
34	-	-
33	-	
32	-	-
31	-	-
30	-	1
Total	201	366

[1] Ausgleichung der Beobactungsfehler.

Let us find the probable error of each average. We have the formulæ, $r_0 = .6745 \sqrt{\frac{x\,\Sigma^2}{n\,(n-1)}}$ and Peters' approximation formula, $r_0 = .8453 \frac{\Sigma\, x}{n\sqrt{n-1}}$.

By the first formula we have for Americans

Errors	Squares.	Sums.
5.26	27.6676	55.3352
4.26	18.1476	18.1476
3.26	10.6276	63.7656
2.26	5.1076	191.5938
1.26	1.5876	46.0404
.26	.0676	2.5012
.74	.5476	25.1896
1.74	3.0276	99.9108
2.74	7.5076	90.0912
3.74	13.9876	125.8884
4.74	22.4676	89.8704
5.74	32.9476	98.8428
6.74	45.4276	145.4276
Total	- -	852.9476

$$n\,(n-1) = 40200.$$
$$40200)852.9476(.02121.$$
$$\sqrt{.02121} = .146.$$
$$.146 \times .6745 = .098477 = \text{Prob. error.}$$

That is, it is as likely that the true value of the average will fall without the limits 41.8385, 41.6425, as within them. It is an even wager. Calculated by Peters' formula the probable error is .0955.

For Irish boys five years old: —

Errors.	Squares.	Sums.
4.41	19.4481	97.2405
3.41	11.6281	69.7686
2.41	5.8081	180.0511
1.41	1.9881	105.3693
.41	.1681	10.9265
.59	.3481	24.8037
1.59	2.5281	161.7984
2.59	6.7081	275.0321
3.59	12.8881	219.0977
4.59	21.0681	105.3405
5.59	31.2481	31.2481
11.59	134.3281	134.3281
Total	- -	1417.0046

Prob. error = .0694.

In other words it is an even wager that the true value of the average lies without or within the limits 41.6594, 41.5206.

In comparing in general two values M and N with probable errors p and q respectively, for M to be unequivocally greater than N, the following relation must hold, $M-N > p+q$. Let us compare thus the averages we have discussed above. $41.74-41.59 = 15$, $.0985 + .0694 = .1679$. Hence Professor Bowditch's statistics cannot be considered as showing that American boys are taller than Irish at the age of five.

Our criterion does not declare the opposite to be the fact, but simply shows that from the data we can draw no conclusion whatsoever. I propose to call the quotient $\frac{M-N}{p+q}$ the *reliability*. The reliability, then, must be unity or greater to merit our confidence. In the case in hand the reliability is $\frac{53}{100}$ — rather small for the number of observations.

Let us compare the heights of Boston schoolboys of American and Irish parentage between the ages of seventeen and nineteen. I shall use the approximation formula $r_0 = .8713 \frac{\Sigma\, x}{n\sqrt{n-1}}$ which gives very close results. This differs slightly from Peters' formula.

Ages between Seventeen and Nineteen.

AMERICANS. Errors.	IRISH. Errors.
7.55	4.80
6.55	6.60
5.55	5.60
13.65	3.20
24.85	.20
20 50	6.00
29.45	2.20
7.15	16.00
8.10	4.20
30 45	6.20
31.85	8.20
24.15	.20
40.05	.80
10.90	3.60
12.90	2.80
14.90	
12.45	169.88)75.20(.44
13.65	
21.30	.44 × .8713 = .383 = Prob.
7.65	error for Irish.
10.85	Prob. error for Americans =
6.05	.15.
4.95	
17.40	
10.35	
14.70	
4.45	
5 45	
6.45	
424.25	

$\therefore M-N = .25$, $p+q = .51$. Reliability = .40. Hence from Professor Bowditch's tables we are not warranted in drawing the conclusion that American boys between the ages of seventeen and nineteen in Boston are taller as a rule than Irish boys of the same ages. Between the ages of six and sixteen the reliability is greater than unity, reaching a maximum for the age of fourteen, and progressively decreasing in either direction. This shows, then, quite conclusively, that poverty and deprivation have an effect in retarding the growth between the ages of six and sixteen, reaching a maximum at fourteen years. The decreasing reliability after fourteen would tend to show that it is a retardation only, which has a tendency to correct itself as years go on. Whether the gap ever closes itself, and if so, at what age, are questions which cannot be answered at present. We have just seen that, as far as Professor Bowditch's tables are concerned, we are not at liberty to say that the gap exists at the ages of seventeen and nineteen.

Boudin is of the opinion that the stature is independent of comfort and misery, but closely connected with race. I think this is highly probable, though it is well to bear in mind that this is in the nature of a personal opinion. Boudin arrived at his conclusions from an examination of the measurements of recruits to the army from different parts of France. His conclusions were not derived from an application of the laws of probability and hence cannot possess the indisputable character of the conclusions I have drawn above.

Villermé concludes as the results of his observations

that "the stature is greater and the growth sooner completed, other things being equal, in proportion as the country is richer and the comfort of its inhabitants more general." This is a hasty conclusion. I have no data at hand by which rigidly to test these hypotheses. But my object in this paper is not the carrying out of anthropological investigations, however interesting they may be, but merely the exemplification of general principles. I believe, however, that if Villermé had applied some of the preceding rules, he would have found that the reliability of his conclusions fell below unity. The method in hand, therefore, furnishes us with a means of *settling* many questions which are at present unnecessarily considered *sub judice*.

Returning to Professor Bowditch's tables, let us compare the weights of American and Irish children at the age of eight years.

AMERICAN.	IRISH.
Errors.	Errors.
29.57	21.88
25.57	89.40
21.57	152.68
70.28	514.02
81.42	835.38
334.95	709.66
334.20	210.04
153.86	259.44
267 30	184.14
430.81	64.92
208.60	14.82
57.72	
	3056.18
2015.83	

Reliability = .81.

Weights between Seventeen and Nineteen.

AMERICANS.		IRISH.
123.88	42.06	32.60
41.94	65.94	28.60
67.88	41.94	33.20
29.94	33.94	12.60
25.94	29.94	17.20
131.64	25.94	18.40
35 88	43.88	1.20
83 64	17.94	22.20
159.04	69.70	11.40
77.22	59.64	61.60
15.52	59.40	19.40
20.60	9.70	81.20
78.78	20.60	43.40
140.84	48.48	
168.72	50.30	383.00
162.54	70.30	
66.18	18 06	
26.06	68.12	
60,12		
136.24	2506.54	
38.06		

Reliability = .89.

The reliability at and before eight years falls below unity; hence we have no grounds for believing that American children in Boston up to eight years of age, nor after seventeen to nineteen years, are heavier than Irish children of the same ages.

Between these ages the fact is declared. The inference from this would be that deprivation retards the acquirement of the normal weight, though its effect in this respect is not so soon developed as in regard to the height. It seems to be equally soon effaced, however.[1]

[1] In comparing the heights and weights above *singly*, where the reliability falls below unity no conclusion can strictly be drawn. However, where the values are *uniformly* in excess in one direction, a presumption is created on that side. But the fact is not *declared* unless the reliability exceeds unity.

Comparing American and Irish schoolgirls in Boston, we find that the height of the latter becomes less than that of the former somewhere before the fifth year. As Professor Bowditch's tables do not record before this age, we cannot say at what year. His tables would seem to show that the gap is closed between the seventeenth and nineteenth years. As regards the weights, they differ reliably at six years and coincide again at the ages seventeen to nineteen. The reliability for five years, comparing the weights, is .45. Hence we see that in girls as well as boys deprivation affects the height before the weight, and in girls both are affected sooner than in boys. We have also reason to believe that these discrepancies are all simultaneously obliterated at the ages seventeen to nineteen.[2]

The method I have exemplified above is a valuable one, and capable of extended application. Take, for instance, the question whether an increased amount of urea is eliminated during increased bodily exertion. Let a sufficiently large number of observations be made under the two conditions of rest and work, the weight being preserved, and other circumstances identical in each case. Then compare the sum of the probable errors with the differences of the averages. I have not any figures at hand, and this paper is already too long without their addition.

But I will say that if the supporters of Liebig's theory will simply show that $M - N > p + q$ in a large number of observations they will do more to establish their conclusions than by any amount of collateral argument. How many theories are there, when so tested, that will fall to the ground! It is these unsound hypotheses, supported by figures, that are especially dangerous. To the average reader the figures furnish them a stability they do not possess.

The following are a few problems in probabilities, given without demonstration, that will possess, perhaps, some utility. Suppose that a complete event μ is made up of two parts m and n; the limits of error of the fraction $\frac{m}{\mu}$ will be $\pm 2\sqrt{\frac{2mn}{\mu^3}}$

For instance, Dr. John Homans out of 100 cases of ovariotomy has had 87 recoveries and 13 deaths. What, by *a priori* reasoning, will be the limits of his success in future operations, under similar circumstances?

$$\text{Here } 2\sqrt{\frac{2mn}{\mu^3}} = \frac{9\frac{1}{2}}{100}$$

Hence, from Dr. Homans' past record, we could not expect a fewer number of recoveries than 77½ per cent., nor a greater number of successes than 96½ per cent. By taking a larger number of operations we shall be able to get narrower limits than these.

Suppose that out of μ cases of scarlet fever, m are followed by acute nephritis, — what is the mathematical risk that it will occur in a given case. The risk is anywhere within the limits $\frac{m}{\mu} 2\sqrt{\frac{2mn}{\mu^3}}$.

This expression must be filled out from statistics.

[2] It is evident that the distribution of observations on each side of the average may be represented by the curve of probabilities. Quetelet, in his tables, erroneously states that the distribution follows the law of the Binominal Curve. V. Bowditch's tables.

Suppose an experimenter has been investigating the prophylactic value of belladonna in scarlet fever. Suppose that out of b people who have put themselves under the supposed influence and have subsequently thoroughly exposed themselves, m do not have the disease. Suppose that w other individuals expose themselves under similar circumstances without taking belladonna and of these m' fail to have the disease. Suppose that in each case, n and n' individuals respectively contract the disease. The case is made out only on the condition $\frac{m}{b} - \frac{m'}{w} > 2\sqrt{\frac{2mn}{b^3}} + 2\sqrt{\frac{2m'n'}{w^3}}$, and this condition is as inexorable as the law of the Medes and Persians. It is in such a way as this that Medicine is to approximate to an exact science. The more heavily she leans upon her sturdy brother Mathematics, the quicker and surer will her progress be.

If an event occurs n times in succession, the probability that it will occur m times more is, irrespective of conditions peculiar to the question, $\frac{n+1}{n+m+1}$.

If an occurrence has been observed to repeat itself n times consecutively, the probability that there is a cause behind it is $\frac{2^n+1-1}{2^n+1}$. Thus: suppposing that every person not vaccinated is certain, if sufficiently exposed, to contract small-pox, and suppose that ten vaccinated persons after greatest exposure fail to contract natural small-pox. What is the probability that the vaccination is the cause of the immunity? Our formula tells us Prob. $= \frac{2047}{2048}$ which is almost a certainty.

I have thus shown that probabilities may be of value in medical investigations, particularly in statistical work.

SANITARY FOREST-CULTURE.[1]

BY J. F. ALLEYNE ADAMS, M. D., OF PITTSFIELD.

THE subject of Forestry, involving as it does important considerations of public health, is not unworthy of the attention of this Society. Although a love of trees has always existed as one of the better instincts of mankind, it is only within comparatively few years that the evils resulting from the wholesale destruction of the forests have become so well understood as to result in active public measures for their prevention. Out of the necessity for overcoming these evils have arisen the science and art of Forestry, whose two-fold aim is to prevent the destruction of forests from being carried to a dangerous extreme, and to reproduce in part those which have already been destroyed. The subject, which was formerly viewed chiefly from an economical point of view, is now, as recent observations bring out more clearly its sanitary aspects, naturally regarded by the medical profession with increasing interest.

The beneficial influence of forests upon public health is chiefly exerted in three ways: —

(1.) By regulating the flow of streams.
(2.) By modifying the climate.
(3.) By protecting against malaria.

[1] Read before the Massachusetts Medical Society, June 11, 1884, and recommended for publication by the Society.

Under each of these heads a great number of interesting facts have been collected, of which the briefest possible summary will be presented.

(1.) It is well known that a piece of woodland acts as a reservoir, a large portion of the rainfall being held by the roots and spongy soil, from which the sun's rays are excluded, thus keeping the springs alive, and storing up water to feed the streams during the dry season. On open ground the snows of winter chiefly expend themselves in spring freshets, while the snow which falls in the woods melts slowly, and is chiefly absorbed by the unfrozen soil. When, therefore, a country is denuded of its woods, the rain which falls upon it is wasted, running off in destructive floods, washing the lighter soil away from the hillsides, overflowing the valleys, and doing a vast amount of damage; while in summer the springs dry up, the streams are shrunken, and those great areas which had been overflowed become dry. A large territory in the southeast of France, once fertile and prosperous, has from this cause become desolated and almost depopulated, and all the rivers of Europe are subject to greater fluctuations than formerly. The same has been observed of the rivers of India, Tartary, and both continents of America. In the United States the increase of both floods and droughts is strikingly apparent. Wherever forests have been allowed to grow up again, on land once cleared, the springs have been found to reappear and the streams which they feed to regain their regular flow. Of this many instances might be cited, only one of which, as possessing a somewhat peculiar interest, will be mentioned as an example. It is stated by Surgeon Curran [2] of the Indian army, that the brook Kedron, in Palestine, which has in modern times been nearly dried up, "has recently for the first time in centuries flowed in a copious torrent, evidently in consequence of the numerous enclosures of mulberry and olive groves made within the last few years by the Greek convent." The prejudicial effects upon health of great fluctuations in the level of streams are sufficiently apparent. There must result great variations in the level of the subsoil water, which are recognized as a fruitful source of disease, and also, dependent upon this, great variations in the depth of water in wells, an important factor in the propagation of typhoid fever. Moreover, the alternate overflow and drying of low lands afford the very best conditions for the development of malarial diseases in those regions where the malarial poison exists, and offer the most inviting field for its spread beyond its accustomed limits. Among the causes of the recent epidemic of malarial fevers in Connecticut and portions of Massachusetts, the cutting off of timber from the mountains must be recognized as an important one, for hence the rivers suffer an extensive overflow every spring, while in the summer they are so dried up as to expose a large portion of their bed to the sun's rays. The malarial poison has reached its greatest intensity and has spread most widely in certain seasons of extreme low water.

(2.) *The influence of forests upon climate.* A piece of woodland exercises upon temperature an influence resembling that of the ocean, cooling the air in summer and warming it in winter. It also presents a mechanical obstacle to the violence of winds, besides depriving these winds of the character of excessive

[2] A Plea for Tree Preservation in India, by Surgeon-Major Wm. Curran, A. M. D. Indian Annals of Medicine, etc., Calcutta, 1877, vol. xix., p. 59.

heat, cold, moisture, or dryness. Thunder storms are less violent in wooded than in open districts, the trees acting as electrical conductors. Forests are also believed to increase the rainfall. The experiments of Dr. Anders [1] show that the evaporation from a forest is greater than that from an equal area of water, twice that from an equal area of damp soil, and several times greater than that from dry soil. It would naturally be supposed that this excessive evaporation would, by increasing the degree of saturation of the atmosphere, increase the rainfall, and such has, in some instances, been found to be the case. In Lower Egypt, for instance, where twenty million trees were planted by Mehemet Ali and Ibrahim Pasha, the rainfall has more than doubled within the life of the present generation. The same has been observed in Scotland, and also on the Island of St. Helena. But such is not the result of all observations. For instance, at Marietta, Ohio, where a record of the rainfall has been kept almost continuously since 1817, the rainfall has not been found materially changed, although the country in that vicinity, which was formerly heavily wooded, has now but thirty-three per cent. of woodland.[2] Such apparent discrepancies show the importance of multiplying such observations, and of taking into consideration all other meteorological influences. One point to be remembered is, that rain being usually formed at a great height, sometimes one or two miles above the earth, the quantity of vapor from a forest may be carried by the wind a considerable distance before being condensed into rain.

(3.) *Protection against malaria.* Of the efficacy of masses of trees for this purpose there can be no doubt. Malaria possesses an affinity for leaves, and those of the eucalyptus are believed by many to possess a peculiar power of neutralizing it. It is highly probable, however, that this influence is wholly mechanical, for the experiments of Tyndall [3] show that all minute particles suspended in the air have a tendency to attach themselves to any surface. The air of closed boxes became, in three days, wholly free from suspended particles, all of which had attached themselves to the sides of the box. Various infusions of meat and vegetables introduced into such boxes remained for weeks and months unchanged, while the same infusions exposed to the general atmosphere speedily putrefied, and became alive with bacteria. These experiments are mentioned as showing the probable way in which leaves remove from the air the elements of disease. In all malarial regions a belt of trees interposed between a swampy place and a dwelling is known to be a defense against malaria. In Virginia, a few years since, the cutting away of such a screen rendered a residence unhealthy which had always before been exempt from malaria. The freedom of the Dismal Swamp from malaria has been ascribed to the fact that it is covered with a dense growth of cypress and juniper trees. A century ago Pope Benedict caused the woods to be cut down between the Pontine Marshes and Rome, against the remonstrances of Lancisi. As a consequence the malaria reached the city, portions of which became so fever-stricken that many people were driven away from homes previously healthy.[4] Within a few years the French in Algeria have greatly reduced the prevalence of malarial fevers by planting large numbers of eucalyptus trees about certain marshy spots. The same has been done, with a like result, in Southern France, in Corsica, in Spain, and also by Trappist monks in the Roman Campagna.[5]

To these sanatory uses of the forest must be added the restorative effect of a sojourn among the woods, as shown by the many invalids benefited by a trip to the Adirondack wilderness, the woods of Maine and Canada, and the pines of the Southern States, as well as the advantages derived from woods and groves near cities and towns where children may spend an occasional holiday in the open air.

Although it is the design of forestry, by introducing a regulated and systematic method of cutting, to render the supply of timber perpetual, without materially diminishing the present supply, yet the chief objection to forest preservation comes from those who fear that the lumber interests will thereby be injured. That this objection is not well grounded is shown in the fact that under the present destructive method of cutting, some of our most valuable woods, notably the indispensable white pine, are becoming scarce, and nothing short of a general and earnest attention to the subject of forest preservation can prevent their speedy extermination.

To insure the protection of the existing forests, and the reproduction, to some extent, of those which have been destroyed, it is essential to have —

(1.) A general diffusion of knowledge as to the injuries inflicted upon the country by the unregulated cutting down of the trees.

(2.) The enactment of such laws as will cause the care and replanting of forests to be systematically and intelligently undertaken, and also prevent forest fires.

(3.) The establishment of forestry as a special branch of education, either in separate schools or in connection with agricultural or other colleges, for the training of skilled foresters to take charge of the timber lands.

In Europe there is no lack of interest in the subject, the necessity in the older countries being greater than in ours. Laws for the replanting and protection of forests have, since 1860, been enacted in France, Prussia, Switzerland, Italy, and other countries. The work is chiefly carried on by the governments of these countries, liberal appropriations being made for the purpose, and a large force of foresters employed. For the education of these, numerous schools of forestry have been established, the greater number being in Germany and Austria.

In the United States the interest in the subject is shown by the organization of a Forestry Congress two years ago, at the meetings of which many valuable papers have been read. Several papers have also been presented to the American Public Health Association, and others have been published in popular magazines. The Agricultural Department at Washington has a Division of Forestry, the report of which, by Dr. Franklin B. Hough, in 1877,[6] is the most useful hand-book on

[1] Forests, their Influence upon Climate and Rainfall, by J. M. Anders, M. D., Ph. D., American Naturalist, January, 1882, vol. xvi., No. 1. On the Transpiration of Plants, by the same author, American Naturalist, March, 1878.

[6] Report upon Forestry, prepared under the direction of the Commissioner of Agriculture, 1877. This report is a mine of information.

this subject, and which is still doing valuable work under Mr. N. H. Eggleston, for which Congress appropriates the paltry sum of $10,000 annually. In eleven States there are laws for the encouragement of tree-planting, either by offering a bounty for lands planted with forest trees, or by exempting such lands from taxation for a term of years. Seven other States have laws to promote tree-planting upon highways. In 1873 Congress passed an Act to Encourage the Growth of Timber upon Western Prairies.[1] In the last census a great deal of attention was given to the forests, and the report by Dr. Sargent, now in press, will contain a vast amount of information on the subject.

In Massachusetts a law exists requiring such agricultural societies as receive state bounty to offer premiums for the raising and preserving of oaks and other forest trees suitable for ship timber. In 1878 an act was passed exempting from taxation for ten years lands planted with certain kinds of forest trees. In 1882 a law was enacted entitled An Act Authorizing Towns and Cities to Provide for the Preservation and Reproduction of Forests.[2] Under this act cities and towns may purchase lands to be preserved as forests. The title of such lands vests in the Commonwealth, and the State Board of Agriculture is made a Board of Forestry, with power to appoint keepers, and to make improvements, though the expenditure in any town may not exceed the amount received for rent and sale of products.

The Massachusetts Society for the Promotion of Agriculture has at various times, beginning in 1804, offered prizes for the cultivation of forest trees. One of these of $1000 was paid in 1870 to the Hon. Ben. Perley Poore, of Newburyport.[3]

In 1872 Harvard University received a bequest from the late James Arnold, of New Bedford, for the purpose of founding a professorship of tree-culture, and creating an arboretum in connection with the School of Agriculture and Horticulture at the Bussey Place, West Roxbury. Thus began the "Arnold Arboretum," which, under the care of Prof. C. S. Sargent, is destined to become an important centre for forestry education.

It is thus evident that Massachusetts has been a leader among the States in regard to forestry, and yet the practical outcome of what has hitherto been done is not very great. The law passed two years ago was specially intended to effect the preservation of the Middlesex Fells and their conversion into a public park, with the double purpose of improving the watershed of the streams and ponds in that vicinity and of maintaining a sylvan health resort. This is an important step forward, and yet the law is not likely to result in any general purchase of forest and waste lands by towns and cities. Such purchases would be most likely to be made for the purpose of improving a water supply, but the fact that the water supply of one town is very often derived from another town, while this law only permits towns to purchase lands within their own limits, renders the law of but little use for this purpose. The same objection will apply to the improvement of the reservoirs of manufacturing companies, since the streams which feed them seldom arise in the same town, and sometimes not even in the same county or State. It has been suggested that the State might charter forestry corporations, composed of manufacturers and others whose interests are involved, with power to purchase and hold large tracts of forest land; but the antipathy of our people to great land monopolies would doubtless render the passage of such a law impossible.

The benefits to be derived from forest culture are not sufficiently local in their character for such work to be assumed with the best success by either towns or corporations. The forests in one part of the State benefit the whole population, especially in the ways which have been outlined in this paper, and, therefore, the wisest plan would be for the State to assume control of the forests, purchasing such lands of little value for farming purposes as may seem advisable, and planting them with forest trees. From these lands the State would in the future receive a revenue from the sale of timber, to be cut under such a system as to insure the perpetuation of the forest.[4] To obtain the very best results such measures should be undertaken by all the States, and when a beginning is made by one or more States others will be likely to follow their example.

Upon the hills of Western Massachusetts are thousands of acres of land, which, when first cleared, was sufficiently productive; but the soil, no longer held together by the roots of the trees, has had its lighter and richer portions washed out year by year until its best elements have found their way into the valleys, leaving the hill farms sterile and nearly worthless. The change is evidenced by the ruined houses and half-obliterated cellars which are sadly abundant on the hills, indicating a population and prosperity in former times which would now be impossible. In the vicinity of Boston, within my recollection, many fine tracts of woodland have been cut down for fire-wood, leaving barren, rocky hills, looking desolate enough without their once beautiful covering. If these sterile hills, all over the State, could be planted with the best varieties of forest trees, and properly cared for, the value of adjacent lands would be enhanced, our streams would flow with greater regularity, freshets and low water would both be less common, the climate would be tempered, the extremes of heat and cold being less marked, and winds less violent, the rainfall would be more copious and regular, malaria would lose its foot-hold, while every grove would be a sanitarium for the weary denizens of city and town. Let us as physicians do what in us lies to promote this important reform.[6]

Dr. Hough also published, in 1882, a valuable text-book entitled The Elements of Forestry.

[1] United States Statutes at Large, vol. xvii., Forty-Second Congress, 1873.

[2] Acts and Resolves of Massachusetts, 1882, p. 200, chap. 255.

[3] Tree-planting on a large scale has been successfully practiced by the late Richard S. Fay at Lynn, and Mr. Joseph S. Fay at Woods Holl.

[4] Private enterprise alone would accomplish much if the art of making forest cultivation profitable were generally understood. In the three western counties of Massachusetts the planting of sugar maple trees would in time yield rich harvests of maple sugar.

[6] Valuable works of reference, besides those mentioned, are the following: Trees and Shrubs of Massachusetts, by George B. Emerson, 1846. Man and Nature, by George P. Marsh, 1864. The Earth as Modified by Human Action, by the same author, 1874.

Also the following books by John Crombie Brown, LL. D.: Forests and Moisture, or Effects of Forests on Humidity of Climate. Edinburgh, 1877. Reboisement in France. London, 1880. Pine Plantations on Sand Wastes in France. London, 1876.

A special bulletin of the Boston Public Library in June, 1879, under the heading Trees and Forests, contained 180 titles. A bulletin printed in connection with the meeting of the Forestry Congress at Washington, May 7, 1884, contains a list of 167 papers read at the previous meetings of the Congress during the past two years, of which a considerable number pertain to the effect of forests upon climate and health. A weekly journal of forestry, entitled Oesterreichische Forst-Zeitung, is published in Vienna.

LABOR IN A CASE WITH CONTRACTED CONJUGATE: VERSION AND CRANIOTOMY.[1]

BY W. E. BOARDMAN, M. D.

FEBRUARY 24, 1884, at 1.30 P. M., Catherine H. was brought from Brighton to the Boston Lying-In Hospital by Dr. H. E. Marion with the following history: Married and had one miscarriage about one year ago. Catamenia last present May 20, 1883, when it was observed that the flow lasted only a day or two, and was scanty. Labor began at six P. M. February 23d. Seen for the first time by Dr. Marion at 12.30 A. M. February 24th, when the os was found to be fully dilated, head presenting O. R. A., but very high, so that he did not feel positive about his diagnosis. At 1.30 A. M. the bag of membranes reached to the vulva, and was ruptured during a digital examination. At ten A. M. no progress had been made; the head was still situated high up, barely within reach of the index finger. Concluding that operative interference was demanded, Dr. Marion hesitated to undertake it at the home of the patient in consequence of the very limited accommodations and arrangements afforded, and advised her to enter the hospital, where she arrived at 1.30 P. M.

Upon examination directly after her entrance the condition of things was found to be unchanged, and I thought I could make out some shortening of the conjugate diameter with the presentation O. R. A. in confirmation of Dr. Marion's diagnosis. It was decided to interfere on account of no progress made and the increase in the rapidity of both the mother's and fœtal pulse, and thinking it would be a favorable case for the employment of Tarnier's axis traction forceps I requested my colleague, Dr. Richardson, to join us, and bring his instrument. In the interval the patient had several strong pains, which Dr. Marion remarked were stronger than he had observed during the progress of the labor. Ether was administered at three P. M., Drs. Richardson, C. M. Green, and Marion being present. It was then found that an error in diagnosis had been made unless possibly a rotation had occurred under the pains in the interval since the preceding examination, for now it was found to be O. R. P. with extension, but the head had not engaged. The idea of employing forceps was abandoned, and version was done with considerable difficulty owing to the firm uterine contractions. Upon the delivery of the body my hand had become useless from the continued pressure to which it had been subjected, and I was obliged to yield the completion of the operation to Dr. Richardson. With much difficulty the arms were released by him, when I attempted to apply forceps after traction had been employed by the body without success. Finding myself unable to adjust the first blade, and thinking it due to the loss of power in my hand, I again gave up to Dr. Richardson, who completed the delivery. He, too, was unable to apply the forceps, and after still further ineffectual attempts to deliver by means of traction on the body I advised perforation of the head as the cord was pulseless when first it came within reach. Accordingly Dr. Richardson perforated with Braun's scissors behind the left ear, not using the trephine through fear of implicating the bladder. Braun's cranioclast was then introduced, but the head could not be extracted. The cephalotribe was tried, but could not be adjusted. The head was then again perforated behind the right ear, the cranioclast introduced, and by combined traction upon this and the body, the child was finally delivered at 4.15 P. M., the placenta following directly. The cervix was found to be badly lacerated in several directions, and the perinæum torn irregularly through the sphincter, requiring several sutures. The child was a boy, and weighed, minus the contents of the skull, nine and one half pounds.

The patient has had a normal convalescence, except that an enormous fæcal discharge on the fifth day tore away the sutures in the perinæum, though the sphincter had united tolerably well. She will return home on the 9th inst., the fifteenth after entrance, at her own request. During her stay in the hospital it has been ascertained that four years ago she was delivered naturally of a good-sized child, though the labor was somewhat tedious.

Measurements with the pelvimeter gave the following results: Between anterior superior spines, eight and one fourth inches; between crests of ilium, nine and three fourths inches; between sacrum and pubes, seven and one fourth inches. Deducting from the latter three and one half inches, an accepted average, for integument, fat, etc., and this patient was excessively fat, we obtain a conjugate diameter, fairly estimated, of three and three fourths inches, corresponding with the measurement obtained by the introduction of the index and middle fingers within the vagina to the promontory. At all events there was some shortening of this diameter. Add to this fact that of the malpresentation, and also the fact obtained after the delivery that the head of the child was notably unyielding from advanced ossification, and the solution of the difficult labor becomes easy. Judging from the condition of the child's cranial bones, its weight, and the history of the catamenia, it is not improbable that its fœtal life was unusually prolonged.

With regard to measurements made upon the outside, Lusk gives as the normal results, ten and one fourth, eleven and one fourth, eight inches respectively, in the above order, according to which our very fat patient presented a notable narrowing in all directions. As showing that we need not be in haste to interfere in every case where the diameters are shortened, as indicated by the pelvimeter, which is applied externally, I will append the measurements in three cases, all primiparæ, now in the hospital, with each one of whom the labors were natural, and, curiously enough, the first one, with the longest diameters and the smallest child, had the longest labor:—

Case I. Diameters, eight and three fourths, ten and and one half, seven and one half. Labor, O. L. A., fourteen hours. Child, seven and one fourth pounds.

Case II. Diameters, seven and one half, eight and one half, six and three fourths. O. R. P., with rotation. Labor, seven hours. Child, seven and one half pounds.

Case III. Diameters, eight, nine and one half, five and three fourths. O. L. P., with rotation. Labor, four hours, twenty-three minutes. Child, eight and one half pounds. And Case III., with a presentation O. L. P., with the shortest conjugate diameter and the heaviest child, had the shortest labor.

NOTES OF A CASE OF DROWNING.[1]

BY GEORGE STEDMAN, M. D.

ON Thursday, May 22, 1884, the body of an unknown man was found off Wellington's wharf in the water of the Mystic river. The body was that of a man five feet ten inches in height and about one hundred and seventy pounds in weight. He was about forty-four years of age, had heavy red mustache and side whiskers ("Galway sides"). He wore a dark mixed suit, white shirt, and heavy boots; this being all the information known to the medical examiner.

External examination showed no mark of violence except a bruise upon the forehead. There was no frothy foam perceptible at the external air passage, neither was there any strongly marked congestion of the face or upper part of the body, and the body was in an excellent state of preservation. Forty-eight hours after the recovery of the body there was noticed a bluish-purple discoloration of the eyelids; and upon the lower portion of the abdomen, in the iliac region of each side, there was at the expiration of another day a greenish discoloration, somewhat faint, of the size and shape of half a pea-pod.

Though from the place of finding the body, death was presumably from immersion, the fact of a decomposition developing at the abdomen primarily, and the discoloration about the eyes, which in the absence of any other appearance of decomposition about the face and head, taken in connection with the bruises on the forehead, suggested that there might be a fracture at the base of the skull, and an autopsy was decided upon.

At the time of examination, which was four days and a half after the recovery of the body, the appearances which have been mentioned had not materially changed, except that the discoloration about the eyes appeared more like the discoloration of decomposition than like the ecchymosis of a fracture.

On section there was found to be very little if any congestion of the vessels of the brain.

The right heart was in no way distended with blood, and a portion of the blood in the right auricle was clotted.

The lungs were not increased in volume, and only moderately congested, neither did the section show the presence of water in these organs to anything beyond an amount which might have been readily overlooked.

The stomach contained about a teacupful of water. The other internal organs, aside from a very slight amount of congestion, presented nothing unusual.

While all these appearances are consistent with each other, and consistent with death from drowning, which in the absence of any other cause of death discovered post-mortem, and in view of the history of the case, is undoubtedly the correct diagnosis, the case is of interest from the absence of almost all the typical signs of death from drowning, and by the presence of some of the appearances which are supposed to contraindicate such cause of death.

The probability is that the man fell into the water, and in falling struck his forehead, producing insensibility, that he immediately sank, and being insensible he made no attempt at inspiration, thereby getting no water into the lungs. The fact that there was no struggling would account for the absence of the intense congestion generally seen in the upper parts of the body. Hence the developing of the process of decomposition in the usual manner.

CHLORAL HYDRATE AS AN ANTISEPTIC.

BY E. WARNER, M. D., OF WORCESTER, MASS.

FOR the last ten years I have used a solution of chloral hydrate as almost my only surgical dressing. This has met the conditions so perfectly, I have not been tempted to substitute for it any of the other dressings that have met with favor among those making use of antiseptic treatment.

It makes a clear and clean solution, itself without offensive odor, and with power to remove the odor of carbolic acid or the fœtor of purulent discharge.

It is not only not irritating, but it seems to act as a local sedative or narcotic, often relieving the pain of a recent injury or operation so completely as to make the use of an opiate unnecessary.

It leaves no stain; can be sprinkled freely on the floor as on the clothing, and its use is no way disagreeable. It is inexpensive and simple in its application.

A solution of the strength of from three to five grains to the ounce will be found sufficient for all ordinary purposes.

In the treatment of large suppurating wounds or granulating surfaces, it will often keep the air of the room or ward so pure that no one would suspect the presence of such a case. There is no danger from its absorption, but much comfort follows its constant employment. The spray is not used during the operation, and no heavy, thick, and somewhat bungling dressing afterward. A light and moist dressing is all that is required. After properly cleansing the wound with this solution, adjust by suture or strap the flaps or edges of the wound as accurately as possible. Make use of a light compress moistened with the solution, and apply the roller with only sufficient firmness to keep the parts from bagging or the flaps from becoming œdematous and flabby. If necessary leave some dependent point open for drainage, and use no drainage tube unless its use seems imperatively demanded. The presence of the drainage tube usually prevents union by first intention.

This warm, moist, light, and clean dressing will prove soothing and agreeable to the patient, and can easily be changed as often as is required for cleanliness, as the dressing is not allowed to become dry and sticky. Somewhat frequent changes add to the comfort of the patient and insure perfect cleanliness. This tends also to relieve the surgeon of anxiety, and he watches less nervously the pulse and temperature to apprise him of the approach of threatened danger, as is the case when the wound is concealed under the numerous folds of the Lister dressing.

There need be no fear of bacteria entering the exposed wound. They are effectually destroyed by the dressing; the soil becomes unsuited to their development and growth. It acts as a perfect germicide, and this is why the spray is discarded, which is an unpleasant and troublesome part of Listerism.

For use during the operation a solution made with warm water is preferred. In this the hands of the operator are cleansed, the sponges, instruments, liga-

tures, and sutures are also all passed through it. Following this practice healing by first intention is often secured after many of the major amputations of limbs and breast, where suitable flaps can be obtained. Compound comminuted fractures, with great injury to the soft parts and very free oozing of blood at first, will often heal without suppuration.

What of the solution penetrates the wound seems to destroy the offending germs, and prepares the wound for healthy reparative processes.

Seldom, if ever, has a case operated on for injury or disease, and treated by chloral, thoroughly applied, been followed by pyæmia or septicæmia. This is claiming much, but the records of hospital and private practice sustain the assertion.

Examples can be given from all departments of surgical practice where it has been exclusively used. It has been most thoroughly tested in cases of ovariotomy, and with the most gratifying success. With my present experience of its use in this operation I should be unwilling to use carbolic acid or any other antiseptic with which I am now acquainted. In this important operation it seems to be *the* agent *par excellence* which should be used where a surface so extensive and so delicate and parts so vital are exposed, and sometimes requiring a somewhat lengthy exposure. It never poisons; it never irritates; it never does any harm. So far as present experience shows its effect is only soothing, cleansing, and wholesome.

In midwifery its use is entirely satisfactory. As an injection it disinfects uterus and vagina, and is in itself always safe.

In the operation for restoring the perinæum or the cervix, or as an injection after any operation in uterine surgery, it meets all the conditions of a safe and reliable antiseptic remedy.

Its use is equally satisfactory in the treatment of felons, abscesses, fistulæ, etc., after operation. It is one of the most soothing of applications in burns, erysipelas, eczema, and chronic ulcers.

An obstinate case of chronic eczema, about the ankle-joint of a hysterical patient, was cured in a week by simply keeping a cloth on it constantly wet with this solution. The dressing was not allowed to become dry for a moment, night or day, for a week, when the cure was complete. This case had lasted many months, and had perplexed more than one physician.

Chloral can be used with vaseline or glycerine in the same proportions of three or four grains to the ounce, if for any reason it is more desirable to use it in this manner.

It is not necessary, perhaps, to use more space for the purpose of citing illustrative cases or of demonstrating its method of use more in detail.

The evidence in favor of the other members of the antiseptic family, as given from time to time in the journals, has been faithfully followed, and duly considered.

The object of this paper is simply to call the attention of physicians and surgeons to this antiseptic remedy, the use of which has been attended with satisfactory results in the practice of the writer and those who have been so situated as to observe its use. This family is already large, but is still on the increase.

The perfect dressing has not yet been found. The field of experiment and trial is being thoroughly cultivated, and almost any one may contribute something of value to the general result.

Chloral hydrate in solution is clear, colorless, and well nigh inodorous, harmless and inexpensive, and yet thoroughly efficient; can be easily kept and transported, as two ounces of water will take an ounce of the crystals, and thus it can always be had when and wherever needed. No accidents or serious mistakes can follow the use of this weak solution of three or four grains to the ounce, but comfort will be contributed to the unfortunate sufferer.

REPORT ON MEDICAL CHEMISTRY.

BY WILLIAM B. HILLS, M. D.

COPPER.

THE action of solutions of salts of copper on animal membranes has long been known and investigated, but much remains to be learned, especially about chronic copper poisoning. V. Ellenberger and Hofmeister[1] record their observations on the effects of small doses of the salts regularly administered. The subjects of the experiment were sheep, and the dose of from half a gramme to three grammes. Amongst the negative results were no alteration of muscular structure, no acceleration of the motion of the heart, no uniform alteration in the microscopic appearance of the blood corpuscles, no alteration of the respiration nor of the secretion of urine. Amongst the positive results, the presence of albumen, bile, and blood in the urine, flaccidity of muscles, weakness, and loss of appetite. The excretion of copper from the system is chiefly by means of the bile, partly by the urine, but in lesser degree.

The principal part of the body which retains copper is the liver, which holds it with very great tenacity, it having been found forty-one days after a dose had been given; the pancreatic glands retain it with almost equal strength; the kidneys do not contain so much as the other two organs. The deposit of copper is proportionally much greater if it has been administered in numerous small doses, the cells having time to absorb it, which is not the case with large doses, owing to their rapid action. The deposits in the nervous system are small, and still smaller in the muscular system: not enough to interfere with their action, but sufficient to be found in the flesh after administration of medicines containing copper.

The opinion is entertained by many that copper should not be classed among the poisonous metals. In large quantities it is, of course, noxious: but this is true of many substances which cannot fairly be considered as poisonous. The latest experiments tend to indicate that, at any rate, copper is not a cumulative poison like lead. MM. Houlès and De Pietra Santa,[2] in a recent communication addressed to the Académie des Sciences of Paris, give an account of Durfort, a village of Tarn, where the workmen pass twelve hours daily in the midst of an atmosphere of copper oxide. Their skins, hair, and beards are covered with copper. The same metal can be detected in their secretions and excretions, and after death in their bones. These people suffer from no special trade disease, and on the other hand they enjoy no special immunity from infectious

[1] Journal of the Chemical Society, London, April, 1884, page 474, from Bied. Centr, 1883, page 606.

diseases, and in particular from cholera and typhoid fever. The reporters conclude that the so-called "colique de cuivre," asserted in the eighteenth century to be a definite disease, does not exist.

ATROPINE.

A. W. Gerrard, F. C. S.,[1] describes a test for atropine which he believes will be of value in forensic analysis, as hitherto no reliable chemical test for this alkaloid has been known. For practically working the test he recommends the following procedure: To a small portion of atropine in a test-tube, add about two cubic centimetres of a five per cent. solution of mercuric chloride in fifty per cent. alcohol, and warm gently; a yellow precipitate at once appears and becomes brick-red in color upon boiling. He finds there are certain conditions necessary for the success of this test, as is the case with most alkaloidal reactions. It does not answer in dilute solutions, neither does it turn out well if the atropine be added to the mercury solution. The mydriatic alkaloids, hyoscyamine, daturine, duboisine, and homatropine give the same reaction. The same test was applied to other alkaloids. They gave for the most part a white precipitate; in no case a red precipitate.

ELIMINATION OF MERCURY IN THE FÆCES.

Schuster[2] states that in forty examinations of fæces, mercury was found regularly in relatively large quantities during treatment by inunctions. Mercury was found in the fæces for five and one half months after the end of the mercurial course. The metal was found in the fæces in all the cases in which it was found in the urine; on the other hand, it was frequently not present in the urine when it was found in the fæces. The inference is that the elimination of mercury by the fæces is regular and continuous, and that after extensive courses of inunction, say of from thirty to forty-five days, it is completed in six months.

POISONING FROM BAD MEAT.

According to Huber (who treated the subject in 1878 in the Archive der Heilkunde),[3] the above title applies to a group of diseases which, though possessing various features in common, have been often mistaken by reason of their peculiar causes. Huber alludes to the uniform and characteristic features of these cases, which he divides into two groups. The shorter form of the disease quickly manifests itself (sometimes in a few hours) after the poison has begun to operate, convalescence or death ensuing in a few days. Excessive vomiting, violent colicky pains, indifference to surrounding objects, rapid failure of strength, extreme feeling of cold, cramps in the muscles of the calves, and low temperature of the skin in all parts of the body, are referred to in connection with this form of the malady. In fact a certain resemblance between it and cholera is pointed out. Extreme weakness and occasional shivering only introduce the special appearances connected with the disease, which manifest themselves in the digestive canal and the nervous system. Vomiting and diarrhœa, followed by constipation, indicate the derangement of the former; while the affection of the latter is shown by great excitability, and occasionally by sleeplessness and delirium. The slower form of the disease is, however, considered the more fatal. The interval between the infection and the appearance of the disease is usually six days or more. The preliminary symptoms may then last some days, and the actual outbreak of the disease is attended rather by constipation than by vomiting and diarrhœa, while the most serious disturbances in the nervous system are noticeable. Feverish appearances are also present, as well as a decided increase of temperature. These symptoms are followed by cramps in the muscles (particularly the calves), hoarseness and aphonia, oppression in the chest, and violent palpitation of the heart. Convalescence is slow in both cases, and the smallest mistake in diet is apt to cause a renewal of the above symptoms, or even a complete relapse.

PTOMAINES.

Thomas Stevensen, M. D.,[4] gives a brief account of the recent investigations in regard to the alkaloidal bodies discovered by the late Professor Selmi in 1872, and to which he applied the name of ptomaines. In 1880 the Italian government appointed a commission to investigate these bodies. A few papers have already appeared from the hands of individual members of the commission, including one from Selmi, who in 1880 described the physical properties of the hydrochloride of a basic body resembling conine. Its physiological effects, however, were similar to those of curare, a result confirmed by Th. Husemann. In 1881 Armand Gautier showed the basic character of the ptomaines by their power to neutralize acids, and by the formation of crystallizable chloroplatinates, like those furnished by the alkali-metals, ammonia, and alkaloids generally. In the same year, this observer, in conjunction with Etard showed that putrefaction begins with the evolution of nitrogen, that various schizomycetous organisms then develop, which attack the albuminoid bodies with evolution of hydrides of sulphur and phosphorus; whilst leucines, leucinines, skatol, indol, carbylamines, and ptomaines are formed. By fractional extraction of putrid liquids with ether, they obtained two bases having the composition expressed by the formulæ $C_5H_{13}N$, and $C_8H_{15}N$ respectively.

Nencki claims to have separated the ptomaines from the products of the decomposition of gelatine by pancreatic tissue; and from one analysis of the chloroplatinate of a base he deduced the formula $C_8H_{11}N$.

L. Brieger obtained ptomaine reactions from peptones prepared by acting on egg-albumen with gastric juice; but the base could not be separated. The extracts nevertheless were poisonous. From a fermented magma of horseflesh in water he obtained the hydrochloride of a base $C_5H_{14}N_2$, crystallizing in needles; but he was unable to isolate the base itself from its salt. Doses of seven or eight grains of the hydrochloride were only feebly toxic to rabbits. The mother-liquid from which the salt crystallized was however more poisonous, and is stated to have contained the salt of a poisonous base $C_5H_{11}N$, isomeric with piperidine.

E. and A. Salkowsky obtained from putrid flesh and fibrine a base which they analyzed and to which they assign the formula $C_5H_{11}NO_2$; but it was not poisonous, and is probably not a ptomaine, but an amide of valeric acid.

The labors of Guareschi and Mosso are most important, tending to discredit much of the previous work

done in this field, and to condemn Dragendorff's method for separating the alkaloids in medico-legal analyses. They find that commercial alcohols are seldom so pure as not to contain bodies reacting like alkaloids; that commercial ether and chloroform need purification; and that ordinary amyl alcohol, and benzine contain pyridine. All experiments made with unpurified reagents are hence necessarily valueless. This circumstance may, perhaps, serve to explain the differences between observers, some of whom have been able, and others unable, to obtain similar results when working with like materials. From so much as eighty pounds of putrid human brains, only insignificant quantities of ptomaines were obtained, too small for analysis; and these, in doses of one fifth to five grains, given to frogs subcutaneously, produced effects like curare, though it required the larger of the above doses to kill the animal. Experiments made with guinea-pigs convinced the authors that the ptomaine of human brains could not be confounded with any known poison in toxicological investigations by its effects upon animals.

From the putrefaction of enormous quantities of fibrine there resulted a base, with alkaloidal reactions, and forming double platinum and gold salts. The composition of this base is represented by the formula $C_{10}H_{15}N$ or $C_{10}H_{13}N$. The discrepancies in the analytical results are not satisfactory. On frogs and birds the extracts containing this ptomaine acted like that obtained from putrid brains. Moreover, fresh brains yielded to Guareschi and Mosso, by the Otto-Stas method, small residues giving the general reactions of alkaloids. Beef, too, yielded minute residues with similar reactions. Fresh materials yielded almost no ptomaines. Dragendorff's method of extracting the alkaloids, in which dilute sulphuric acid is used as the solvent, resulted in more alkaloidal extract than the Otto-Stas method; and there is no doubt that the method of Dragendorff manufactures, so to speak, alkaloids. Coppola also has confirmed these results. He found that fresh dog's blood extracted by Dragendorff's method yielded abundant alkaloidal reactions; not so when extracted by chloroform. The large quantities of putrid material required to be operated on, often one or two hundred weight, to obtain ponderable quantities of a ptomaine, and the small toxicity of the substances thus obtained, except when employed in large doses, show that the probability of a ptomaine being mistaken for a vegetable alkaloid by a careful worker according to the Otto-Stas method is remote.

F. Marino-Zuco [1] states that the so-called ptomaines of Selmi are nothing but neurin.

SALICYLIC ACID AS A FOOD PRESERVATIVE.

The frequent employment of salicylic acid as a constituent of food preservatives makes important any investigations tending to show the effect on the system of the long continued use of this substance. The Comité Consultatif d'Hygiène Publique [2] has on two separate occasions reported against its employment as an agent for the preservation of articles of food. As this conclusion has been much opposed by those interested in such employment, a subcommittee of the body in question has reconsidered the matter, and their reporter, Professor Brouardel, has published their conclusions on this subject in a recent number of the *Annales d'Hygiène.*

He observes that, although the beneficial operation of salicylic acid in certain diseases is fully admitted, the theory of its action is very imperfectly understood. It is known, however, that when introduced into the economy it is eliminated by the kidneys and liver; and its warmest partisans admit that its use is contra-indicated in the subjects of those diseases which prevent its due elimination, and thus give rise to an accumulation that in several instances has proved fatal. Moreover, elimination is sometimes impeded from unknown causes in persons in whom the functions of these organs work healthily, while in aged persons it is always very slow. Under any circumstances, only a portion of the salicylic acid is eliminated, the remainder undergoing combinations in the tissues, which, although they may prove therapeutically useful, and even for a time produce no evil consequences, could not be indefinitely prolonged without mischief ensuing.

Even small doses of the salicylate may prove dangerous to persons who eliminate it imperfectly; and Professor Brouardel's investigations during several years past lead him to believe that the number of such persons is largely on the increase. Since 1861 he has analyzed the urine of all patients entering his hospital service, and his registers show that the frequency of albuminuria has more than doubled during the last twenty years. Now, these patients are not all condemned to an early death, for many recover and others live for many years; and when examples are adduced of young and robust persons tolerating the daily use of from four to six grammes of the salicylates for months or years, we must not forget the aged persons and albuminurics, and individuals the subjects of various kinds of hepatic and renal disease, whose lives might be seriously compromised by such a regimen. The committee, therefore, believing that for such persons the daily use of salicylic acid would be highly dangerous, while even for those in good health there is no proof that it would be innocuous, recommend that its present prohibition should be maintained.

THE DANGERS OF CANNED FOODS.

During the past few years the use of canned foods has become very extensive. From time to time cases of supposed poisoning from the use of such foods have been reported, and in most of the reported cases the presence of some injurious compound of tin has been alleged, although in some cases lead has been identified as the probable injurious contamination. Dr. Henry Leffmann [3] has found, especially in the case of canned peaches, that tin is the metal dissolved. He observes that the solution requires considerable time. In all the cases in which contamination was found by him the fruits were more than a year old. Chemical tests were made on these samples, because they had caused some irritation of the stomach in persons who had partaken of them. Dr. Leffmann mentions a report of A. Winter Blyth, Medical Officer of Health to Marylebone, London, by which it appears that of twenty-one samples of preserved fruits, apricots, tomatoes, and pine-apples, every one contained a dangerous amount of tin, the least quantity found amounting to one and a half grains per pound, the largest to eleven grains per pound.

Dr. Johnson,[4] in a paper read before the New York Medico-Legal Society in April last, cites several cases

of corrosive poisoning supposed to have been due to zinc chloride and tin chloride derived from the use of the "muriate of zinc" amalgam in soldering cans. This flux, consisting of a solution of zinc chloride, is said to be quite commonly used in the place of rosin flux, which is more troublesome, but harmless. Every care is said to be taken in its application, but as it is a poison, some risk of poisoning must attend its use.

Drs. Ungar and Bodländer,[1] of Germany, have recently examined a number of cans of vegetables and fruits, and in every instance found tin in the solid portion of the contents in the form of an insoluble stannous compound. The percentage of the impurity, calculated as metallic tin, was, however, very small, in no case exceeding 0.04 per cent.

Professor Attfield,[2] in a paper read at a meeting of the Pharmaceutical Society, March 5, 1884, expresses the opinion that the action of the fluids or juices of the food on the tin of the can, and consequent solution of the tin, and consequent admixture of a possibly assimilable compound of tin with the food, never occurs to an extent which, in relation to health, has any significance whatever. The occurrence of tin, not as a compound, but as the metal itself, is, if possible, still less important.

During the last fifteen years Professor Attfield has frequently examined canned foods, not only with respect to the food itself as food, and to the process of canning, but with regard to the relation of the food to the can itself. He gives the results of some analyses by which it appears that about one half of the articles examined contained no appreciable amount of tin; the remainder contained varying amounts up to 0.007 grains in a quarter of a pound. The largest amount of tin he ever detected in actual solution in food was in canned soup, containing a good deal of lemon juice. It amounted to only three hundredths of a grain in a half pint of the soup as sent to the table. He thinks that these proportions are undeserving of serious mention; that probably no article of canned food, not even the most acid fruit, if in a condition in which it can be eaten, has ever contained, in an ordinary table portion, as much of a soluble salt of tin as would amount to a harmless or useful medicinal dose; that, if a possibly harmful quantity of a soluble compound of tin be placed in a portion of canned food, the latter will have so marked a metallic taste that no sane person will eat it. This opinion seems to be in accord with the known effects of the very soluble chloride of tin upon animals and man.

Professor Attfield has occasionally met with small pieces of metallic tin in canned foods, perhaps amounting in some of the cases to a few tenths of a grain per pound. These are chipped off from the tin sheets in the operations of cutting, bending, or hammering the parts of the can, or possibly melted off in the operations necessary for the soldering together of the joints of the can, or perhaps cut off by the knife in opening the can. He considers these perfectly harmless. Respecting the globules of solder (lead and tin) that are occasionally met with in canned food, he believes that most persons detect them in the mouth and remove them, as they would shots in game; but if swallowed they do no harm.

He thinks it just possible that in the early days of canning the use of "spirits of salt" in soldering may have resulted in the presence of tin, lead, or other chloride in canned food; but such a fault would soon be detected and corrected. It is just possible, also, that formerly the tin itself may have contained lead, but he has not found any lead in the sheet tin used for canning of late years.

The following are other conclusions to which the author has arrived: (1.) Unsoundness in meat does not appear to promote the corrosion or solution of tin. I have kept salmon in cans till it was putrid, testing it occasionally for tin. No trace of tin was detected. Nevertheless, food should not be allowed to remain for a few days, or even hours, in saucepans, metal baking pans, or opened tins or cans, otherwise it *may* taste metallic. (2.) Unsound food, canned or uncanned, may of course injure health, and where canned food really has done harm, the harm has in all probability been due to the food and not to the can. (3.) What has been termed idiosyncrasy must also be borne in mind. Serious results have followed the eating of oatmeal, shell-fish, salmon, and mutton. Possibly there were cases of idiosyncrasy in the eater, possibly the food was unsound, possibly other causes led to the result, but certainly, to my mind, the tin had nothing whatever to do with the matter. (4.) In my opinion, given after well weighing all evidence hitherto forthcoming, the public have not the faintest cause for alarm respecting the occurrence of tin, lead, or any other metal in canned foods.

PEPTONURIA.

From an investigation of the frequency with which peptone appears in the urine, Von Jaksch[3] has drawn some interesting conclusions. It was found in seventy-six out of 354 cases; seventy-two being instances of inflammation or of pus accumulation, three of scorbutus, and one of phosphorus poisoning. He agrees with Hofmeister in thinking that the peptone is not merely dissolved in the pus (in those cases where pus formation is the predominant feature), but that it is contained in the pus corpuscles. With reference to the cases which were not purulent, he is of opinion that, from the increase of white corpuscles, as well as of the products of their destruction in the blood, it may be concluded that peptone may be set free in the blood by the destruction of these corpuscles, and may be excreted by the kidneys. He gives some examples showing that the onset and course of peptonuria may be of use as a sign of the commencement and cessation of the absorption of inflammatory products.

Hospital Practice and Clinical Memoranda.

A CONCRETION IN THE EXTERNAL AUDITORY MEATUS.

BY DAVID COGGIN, M. D., SALEM, MASS.

An American lady, aged forty-five years, consulted me on the 11th of July last because of deafness in her left ear. The canal was occluded by wax, and after its removal the hearing was normal.

The patient then expressed the wish that the hearing in her right ear might be as easily restored. She stated that there had been a fœtid discharge from it since her childhood, when she had scarlet fever. Of

late years, in spite of her endeavors to keep the ear clean, the odor had been so noisome as to cause her to avoid mingling in society. Watch heard only on contact. On attempting to introduce a speculum, it struck a hard, gritty substance, just within the cartilaginous portion of the meatus. With forceps, this was found to be firmly fixed. By picking it, filaments resembling cotton fibres were drawn out.

The patient said she was positive that cotton-batting had not been introduced in the canal for over twenty years.

Not succeeding in withdrawing the foreign body with the angular forceps, a pair of strong, straight ones was used, and it was only after several trials, and by the employment of considerable force, that the offending plug was removed *en masse*. The lining integument of the meatus was much ulcerated, or bathed in blood and pus. In the lower and posterior quadrant of the drum there was a perforation. After cleansing the middle ear, the watch was heard at five centimeters.

The cretaceous cast of the meatus that was extracted was about twelve millimeters in length, of a dirty gray color, and closely resembled an ordinary pebble. Cotton fibres were readily recognized in the particles of the concretions that were broken off.

Because of the very unpleasant nature of the specimen in the consulting-room, it was at once destroyed, so no careful examination of it was made. Doubtless the deposition on the pledget of cotton, of lime, and other salts from the pus that for two decades was being poured out, resulted in the stalagmitic formation that was encountered.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M. D., SECRETARY.

MARCH 8, 1884. The President, DR. C. ELLERY STEDMAN, in the chair.

LABOR IN A CASE WITH CONTRACTED CONJUGATE.

DR. W. E. BOARDMAN reported a case of labor in which the pelvis was contracted in the conjugate diameter, and in which version and perforation of the aftercoming head were performed.[1]

DR. RICHARDSON said that this was the most difficult and at the same time the most interesting case he had ever seen in the Lying-In Hospital. Considering the long and difficult operation to which the patient had been subjected, it was surprising to see what a convalescence she had. Dr. Richardson also spoke of the advantage of using forceps with the pelvic curve reversed in cases in which the occiput was posterior and the head extended, and he alluded to a case in which he had so used the forceps with success. He thought that after version, when the occiput remains posterior, the forceps could be used to advantage with reversed pelvic curve. In answer to a question by Dr. Lyman as to how high the head was in the case to which he had alluded, when he applied the forceps reversed, Dr. Richardson said that the head was above the superior strait.

[1] See page 176 of this number of the JOURNAL.

DR. C. E. STEDMAN asked what experience members had had with repaired perinæums in subsequent labors. He had had one case in which the new perinæum had not torn in the next succeeding labor. He also inquired how many members had seen fatal hæmorrhage consequent upon laceration of the cervix in labor. He had seen two cases of severe hæmorrhage from lacerated cervix, and also two fatal cases, in one of which the cervix was known to be torn, and in one in which it was thought to be.

DR. HODGDON had seen one case in which a severe pain had lacerated the rigid os and brought the head to the perinæum: hæmorrhage was so severe that the patient fainted before it was controlled.

A SANITARY TOWEL.

DR. CURTIS showed an English sanitary towel for the use of menstruating women: the towel was made of borated cotton, and provided with suitable tapes for adjustment. These napkins were soft, deodorizing and comfortable, and could be thrown away when soiled.

DR. BROWN spoke of an American towel which had been well spoken of: it was made of absorbent cotton and had a thicker band than the English pattern.

DR. DOE had found these towels of value in the lying-in room.

DR. BOARDMAN said that in the Lying-In Hospital a pad was used after labor made of gauze and carbolized charpie: the charpie, he thought, held the secretions better than absorbent cotton.

DIFFICULT DENTITION.

DR. LYMAN alluded to a case of difficult dentition. On two separate occasions, with the advent of the last molars, the child had convulsions followed immediately by severe spasmodic asthma with labored breathing, sonorous and sibilant râles; the symptoms subsided in a few days without treatment, as the local irritation in the jaw passed away. He supposed the pulmonary complication to be purely reflex and similar to the well-known cases of the so-called ear cough.

PLACENTA PRÆVIA.

DR. O. W. DOE reported a case of placenta prævia as illustrating the ease and rapidity with which labor may be induced and completed when this complication arises.

Mrs. J., aged thirty-one, was confined with her first child on the 23d of December, 1879, after a normal labor of twelve hours. Two years and eight months later her second child was born after a very easy and normal labor of three hours: post-partum hæmorrhage ensued directly, which caused a somewhat protracted convalescence. Her catamenia last appeared on May 30, 1883, the second child being then eight months old. Pregnancy caused but little discomfort, though she complained continually of lack of her usual strength.

On February 13th she was suddenly seized with hæmorrhage from the vagina sufficient to thoroughly soak a napkin. There was no pain whatever attending it. She lived out of town, and when I saw her at 3.30 P. M. there had been no recurrence of the sudden flow; but there had been a constant dribbling which had increased during the last half hour. On examination the os was found to be very soft and dilatable, easily admitting two fingers. The head was presenting, but disengaged and freely movable. The placenta

was situated to the left, close to, but not overlapping, the os. Remembering the rapidity with which the cervix dilated at her previous confinement, and knowing that she had a very roomy pelvis, I decided to deliver her at once. To guard against a recurrence of post-partum hæmorrhage, I gave her at four o'clock one fluid drachm of extract of ergot. Ten minutes later I ruptured the membranes and, finding that the head was forcing the placenta before it, I proceeded at once to dilate with my hand, in order to complete the labor by turning. This was accomplished very easily, and the child, a strong, healthy girl, weighing six pounds, was delivered in twenty-five minutes from the time I began the dilatation. The placenta was expelled five minutes later by pressure, and no undue hæmorrhage followed.

The patient made a rapid and uninterrupted convalescence.

DR. FORSTER asked why Dr. Doe gave ergot: the reply was that in a previous labor the patient had had post-partum hæmorrhage, and the ergot was given to forestall the same accident in this case: from his previous knowledge of the pelvis Dr. Doe knew he could deliver the child before the ergot acted.

Medical and Surgical Journal.

THURSDAY, AUGUST 21, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

RECOVERIES FROM INSANITY.

IN the last annual report of the Boston City Lunatic Asylum, Dr. T. W. Fisher, the superintendent, has some interesting remarks on the recovery-rate in lunatic hospitals. He is puzzled to understand the great difference in the recovery-rate between the hospitals of all grades in England and Wales and our own State hospitals. "Why," he asks, "do forty per cent. of the admissions *appear* to recover in the former case, and only twenty per cent. in the latter?" His own percentage of recoveries has been nearly forty, and he cites a number of insane hospitals outside the State in which thirty-five to forty-one per cent. of the patients recovered.

He answers his own question by saying, in substance, that it is largely the personal judgment of the superintendent which leads to the wide discrepancy. In this he is undoubtedly correct, and even to a greater degree than we ordinarily suspect. In the first place, insane hospital superintendents are mortal like other men, and both from temperament and education liable to wide differences of opinion. The morbidly conscientious, over-sensitive, or too scientific man will reject as undetermined that which the over-sanguine and ignorant man accepts willingly as a fact.

The former kind of man will often be in doubt how to classify a case. He will see imaginary symptoms, fear an immediate relapse, or hesitate to try the effect of home surroundings. He is apt to keep a patient too long and lose the golden moment to discharge him, when recovery would be permanently established by so doing. Finally, when too late, the patient leaves, "much improved," but never to be perfectly well. The over-sanguine man, on the other hand, jumps at his conclusions, and by a series of mental gymnastics accomplishes brilliant, not to say startling, results. To him amelioration means recovery, and his patients go home weeks or months before the proper time. His recovery-rate will be large and flattering to his institution. He keeps no table of relapses or homicides committed by discharged patients, and his conscience will be easy.

For the most gifted of men insanity is a disease extremely difficult to understand. There is no fixed standard of mental health, and as truly none of mental disease. Each case is in some feature unlike all others. There may be and usually is some clearly demonstrated physical ailment, existing as a complication. Beyond these questions of mental and physical manifestations, is that of the liberty of the subject. The latter question is one which is sure to become more and more difficult to settle as we better understand the nature of insanity. Some of those patients formerly sent to a "close asylum," so-called, will do better in a small open institution on the voluntary plan, without total deprivation of liberty, and a larger number of cases of incipient insanity, or insanity with a preponderance of moral symptoms, will be sent earlier to a lunatic hospital. As the means of treatment become more varied and scientific, greater skill and knowledge will be required on the part of the alienist to properly use them, for while many diseases do well on the let-alone plan, insanity requires very early and decided treatment to effect its cure. In the decision of all these matters, what Dr. Fisher calls the "personal equation" will have a direct and important bearing on the recovery-rate.

Dr. Fisher speaks of the researches of Drs. Earle and Parks in relation to the recurrence of insanity, and thinks these researches have had a tendency to lower the apparent recovery-rate of the State hospitals. "Recovery and Recurrence," he says, "are two different questions and it is impossible to predetermine the permanency of the yearly recoveries in an annual report." Every patient discharged without trace of insanity and well enough to resume family relations should properly be called recovered. The fact that he has been insane before, or possibly may be again, does not change his condition on discharge. If free at that time from mental disease, he is to all intents and purposes well. We do not think that Dr. Earle's very valuable investigations can change this rule. But undoubtedly they have made superintendents more careful in putting down patients as recovered, and have especially shed light on the *permanency* of *recovery* and in that way added to our knowledge of insanity.

Fifty years ago Dr. Samuel B. Woodward, super-

intendent of our then only State hospital at Worcester, after stating that the average percentage of recoveries for that year had been fifty-five and three fourths,[1] proceeds to compare this showing with foreign insane hospitals. He finds in thirteen in Great Britain an average of thirty-five per cent. In five French hospitals forty-three per cent., and in four German hospitals thirty-one per cent. "Oh! what a falling off is there," we might well say, in looking at our present results. Our recoveries have been reduced nearly two thirds, while England's have materially increased.

If we take another comparison, we find, according to Dr. Fisher's report, that the percentage of recoveries in our four State hospitals for cases of all kinds have been six and one half per cent. Dr. Woodward states that Esquirol for the eight years previous to 1834 had a percentage of recoveries on all cases of twenty-five and one fourth, while at the Worcester Hospital for four years the proportion of recoveries on all cases was thirty-eight and four fifths per cent.

These figures must of course be accepted for what they are worth. From any point of view they show a falling off in the recovery-rate. If we should, however, take other lunatic hospitals, the contrast would be less striking. This, for instance, is the case in Scotland, where, according to the Commissioners on Lunacy, there is a diminished death-rate, an increased recovery-rate, and a smaller increase in incurable patients, than in asylums in other countries. In England the Lunacy Commissioners have said that the increase in fresh cases of insanity is not out of proportion to the increase in population.

Such statements as these make us throw off a little of the deep melancholy into which we have been plunged by reading some of our State Insane Hospital reports. And we even have the courage to assert that our observation and reading have led us to the conclusion that at least thirty per cent. of all cases of insanity admitted into lunatic hospitals are discharged recovered. Of late years the recovery-rate has risen, rather than fallen off.

MEDICAL VERNACULAR.[2]

A SHORT time since the JOURNAL referred to some expressions more or less commonly used by the laity (particularly those of foreign extraction), in describing the state of their bodily health. Some other phrases have since suggested themselves which may also be of interest to mention in this connection.

First, there is a word which is in very general popular use among patients of all classes, but which is applied to very different things. To bloat is in general to swell, and when a person says he "has been bloated" one is apt to understand that there has been œdema. It is the favorite vernacular word for ascitic distention. But it is also applied to flatulence, as when one says that he is "apt to bloat every day after dinner." By derivation this is apparently the more correct use of the word. *Bloat*, to wit, *blowed*, should refer to a distention with gas rather than with fluid. This word is cited to show that what is intended by the patient as a definite term may and often does require further investigation by the physician.

A curious misapprehension exists among the lower ranks of society regarding the word *fracture*. We remember that once having had occasion to make a diagnosis of broken arm in an Irish child, the mother thanked God with great unction that it any way was n't "a fracture," which mishap, it seems, she had once suffered from herself. We have several times observed this peculiar dread of a fracture over and above that of a broken bone (though what was the distinction in the speaker's mind has never been made clear), and recall the awe-stricken way in which, after an opinion had been expressed that no bones were broken, the question was asked, "Do ye think is it a fracture?"

The "spine of the back," an expression which seems at first sight rather tautological, is, perhaps, after all, only an accurate and discriminating utterance. If *spine* (French *épine*) is a thorn, and the vertebral column is so called only by metonomy from the spinal processes which are in the living subject its most obvious part, who shall say that the patient who complains of a bad pain in the "spine of his back," is not speaking with at least scientific accuracy in excluding other spines, as that of the ischium or pubes.

"Doctor, how are my pulse?" is a question often heard in our hospitals. Even those who in general pay no regard to maintaining a correspondence between the number of their nouns and of their verbs, yet draw the line at their imagined plural *pulse*, perhaps out of respect for it as a scientific word. "His hands is cold, but his pulse are good," say such persons. Acquaintance with the sound rather than with the looks of the word is, of course, the obvious explanation of this error. We remember on one occasion to have been fortunate enough to hear the singular *pult*. Yet in general the plural does not presuppose a singular any more than to a carrier of ashes does that term suggest an ash.

"Spits" is good Saxon, and has the advantage in brevity over its Latin brother. "To heave up bad spits" is the fate of many a luckless emigrant to our bleak New England shore. With the native politeness, which is one of the most delightful characteristics of the Irish race, he always adds after any such unpleasant allusion, "saving your presence" or "wid respects to ye." The mention of vomiting is made with similar deprecation unless, indeed, the expulsive effort is ineffectual, in which case it is merely a "dry reachin'."

"A sore troath" is an ailment of frequent occurrence. The transposition of the *t* and the *th* in this word is almost universal among the Irish. The word recalls to us a curious instance of the persistence of an obsolete word which lately came under our observation. A domestic (a Nova-Scotian, we believe,) spoke of having the *squinancy*. No one of the family could

[1] This percentage is based on *discharges*. It would be nearly four per cent. less calculated on *admissions*.

[2] Continued from page 141.

understand what she meant until the head of the household recollected the word as being old English, and used by Bacon. Squinance, squinancy, squinsy, are the successive steps which led to *quinsy*. All, as also the Italian *squinanzia*, the Spanish *esquinancia*, the French *esquinancie*, have a common parent in κυνάγχη (κύων ἄγχω) the "dog-throttling," that choking which is as when one is throttled by a dog. The Latin form, *Cynanche*, has persisted in medicine to the present day, as in "Cynanche maligna," but the cognate English word, squinancy, has dropped so far out of sight as to be at present almost unintelligible, except, strange to say, among the farming population of Nova Scotia.

ANTHROPOPHAGY.

Recent disclosures in connection with the survivors of the Greely Arctic expedition have called attention strongly to the above subject. Evidence obtained from the exhumation of the remains of Lieutenant Kislingbury makes it certain that during the latter period of their struggle with starvation some, at least, of the men made use of human flesh as food. We cannot but regard the persistent efforts of certain newspapers to discover and promulgate these facts as uncalled for, and the surviving friends who have claimed autopsies have, we think, acted unwisely for their own peace of mind in converting what would have otherwise remained an open question, at least in regard to individuals, into a ghastly certainty. There seems to be no evidence and, perhaps, from the nature of the case, never can be any to show that the death of any member of the party was due to violence, except in the case of Private Henry, who was shot by order of the commander after repeated infractions of discipline under circumstances calculated to prejudice the safety of all his companions, and after receiving an exhibition of leniency much greater than would ordinarily be expected of a military commander. The fact that his body was eaten will, of course, raise questions as to the singleness of the motive which caused his execution, but the explanation given seems ample.

Admitting, then, the fact of human remains having been eaten by men in dire extremity, we can hardly understand the public horror at the fact, or the strenuous denials persisted in alike by survivors and government officials. The appropriate feeling seems to us rather to be one of profound pity for those subjected to such distress, and the indignation, if any, should be reserved for those, whoever they may be, who are responsible for the neglect and abandonment of the explorers to the bitter cold and the foodless solitudes of the Arctic shores.

The subject of anthropophagy is one of interest to the ethnologist and the physician. The question has been discussed whether it was practiced by primitive man, and so whether it was to be regarded as a natural instinct. The prevalent opinion seems to be that while there is some evidence that individuals may have eaten human flesh, yet at that period, as now, the majority were not addicted to it. The bones which have been found of this period were mostly intact, and it is argued that were the individuals eaten, the bones would be found broken either as a means of getting off the flesh or of extracting the marrow.

Evidence is not wanting that cannibalism was practiced in countries now the foremost in civilization. St. Jerome, writing about 380, says of a valiant tribe of Caledonia: "Cum ipse in Galliâ viderim Attacottos (vel *Scotos*) gentem Brittanicam humanis vesci carnibus . . . pastorum *nates* et feminarum *papillas* solere abscindere: et has solas ciborum delicias arbitrari."[1]

In the chronicles of the *Welsh Triads*[2] charges of cannibalism are freely made against the Saxon conquerors. Ethelfrith (King of Northumbria, A. D. 593) encouraged it, and Gwrgi, a Welshman residing at the court, became so addicted to it that he would eat no other meat. A man and a woman were slain for him daily, and on Saturdays two of each, in order that the Sabbath might not be broken! But much later than this cannibalism continued to be practiced. Lindsay of Pitscottie, writing in 1460 of what had transpired within the recollection of people then living, tells of a family of cannibals, of whom one, a daughter, had become so enamoured of human food that she said to her executioners: "Give me credence and trow me if you had experience of eating men and women's flesh, ye wold think it so delicious ye wold never forbear it again."[3]

The inhabitants of the island of Shetland are said to have eaten those who were shipwrecked upon the island. Cannibalism was also practiced in the vicinity of Glasgow and of Perth in the fourteenth century.[4]

The eating of human flesh for other purposes than averting starvation is not unknown in later days among civilized peoples. During the French Revolution one of the mob plucked out the heart of the Princess Lamballe, and took it to a restaurant, where it was cooked and eaten by him. Sir Ewen Cameron of Locheil, the great Highland chief, killed an English trooper by taking a bite out of his throat, and used to say that it was the sweetest morsel he ever tasted;[5] a remark almost identical with that ascribed to Richard Cœur de Lion, when, on recovering from sickness and longing for a piece of pork, he could not obtain it, but was given as a substitute a piece of a Saracen's head.

Voluntary cannibalism at the present day has substantially disappeared, except in remote localities. The brown races of Polynesia, until within a few years, practiced it as a religious rite; the New Zealanders only when inflamed with hatred against their enemies; while the Fiji natives almost alone practiced it from actual relish. Pork and human flesh were the only kinds of meat to be had, and the latter was considered the greater delicacy. A writer[6] describes a banquet at which ten bodies were served.

The somewhat curious fact has been pointed out[7] that the people most systematically addicted to canni-

balism are not the most degraded of the human race. The latter types, as a rule, feed on worms and herbs, while the New Zealanders and Hawaiians (both systematic anthropophagi) were much more perfect physically than the Australians, whose small food they despised. A banquet hall in New Zealand in which cannibalism was regularly practiced was a highly ornamented building, "one of the finest specimens yet extant."

Famine, siege, and shipwreck have been the causes of involuntary cannibalism, and at the present time the last mentioned is the only contingency likely to lead to this terrible necessity. The chief question of medical interest is what is the effect upon the bodily organization of such food. The mental influence, of course, should be taken into account, although it is probable that before yielding to this necessity the mind of the sufferer has already reached a point where all other feelings, as of religion, sentiment, emotion, respect, are swallowed up in one overwhelming frenzy for food. After the hunger is in a measure appeased the psychical faculties may regain enough of their normal tone to sink the victim into a state of profound depression. Of course, from the nature of the case, observations must forever be wanting as to the mental state of a starving man.

Physiologically, human flesh is, of course, a nitrogenous food, and as such, under the same conditions as the flesh of other animals, is capable of supporting life. Human milk is one of the most perfect aliments known. Human blood is transfused into the veins of persons exsanguinated, and restores their strength, otherwise irrevocably lost. The taste of human flesh is probably not greatly different from that of the other mammalia. If we could conceive one being fed with it unwittingly, as was Thyestes in the ancient myth, he would probably be none the worse for it — would possibly relish it.

These remarks are qualified by the fact that it is rarely that starving men obtain the flesh of the human animal under circumstances which admit of its having any comparison with that of other animals as a nutriment. Worn out with toil, wasted by hunger, and probably dying of starvation or of disease, the flesh is likely, like any other diseased flesh, to disagree, and to cause digestive disturbance. The exceptional circumstance of a violent death occurring to a man in fair health would furnish a food, probably nutritious, and certainly, as we believe, quite legitimate when the sole means of prolonging life. Even a natural death from certain forms of disease, as, for instance, cerebral hæmorrhage, would probably not materially injure the body for purposes of food. The bleeding of a slaughtered animal, while in accordance with the ancient Mosaic ritual and with modern custom, for the purpose of whitening the meat, improving its flavor, and enhancing its period of preservation,[1] is not absolutely essential, and its neglect in the case of disease supposed, especially in an arctic climate, would probably cause no serious ill effects. Other causes of death, such as septic diseases, those involving fever, tuberculosis, and the like, would doubtless subject the consumer to grave risks.

It is to be wished that those who by such terrible experience of hardship have been brought to the dreadful necessity of subsisting upon the flesh of their dead fellow-men could feel assured of popular sympathy and pity, and that, inasmuch as publicity has been given to the unfortunate facts, we might have such results of their sad experience as may be of physiological value.

[1] Pavy, Food and Dietetics, page 149.

It must be borne in mind that the Greely party when found, and probably for months before, were none of them in a normal condition of body or mind; that famine brings the strong man low down in the animal scale; that under its influence the powers of the mind are progressively suspended, those being first suspended which are the most recent products of civilization, — among them the sense of moral obligation and of decency; that "the normal highest level of evolution, the topmost layer" (to use Hughlings Jackson's phraseology), is rendered "functionless" under the "dissolution" which prolonged want of food occasions; that individuals from hunger and anæmia and emaciation eventually reach a level where the automatic and instinctive impulses are everything, and the voluntary are nothing; that, in fact, there is a lower stage of evolution where, to use a homely phrase, "dog can eat dog," are truths with which physiologists are familiar.

Far, then, from wondering that anthropophagy occurred among the dismal experiences at Cape Sabine, we should look upon it as one of the most natural things that could happen under the circumstances, and the necessity of the situation and the deplorable physical and mental condition of the men should be a sufficient justification of the act.

"In passing by certain pathological conditions where hunger presents itself in an inexorable manner" (we quote from the work of Longet), "we witness similar phenomena in the case of men of previously sound organizations, but deprived of food. We are compelled to believe that in these cases a pathological state supervenes, a particular delirium, the delirium of famine. The starving wretch is under the domination of resistless egoistic impulses. In vain the moral law commands, in vain social laws and customs menace and restrain; hunger speaks louder than law, than reason, than sentiment. It is a matter of history that in years of famine crimes against the proprieties of civilized life increase in a marked manner; in savage countries, where hunting is the principal means of support, cannibalism is often practiced in times of great scarcity.

"Instances of anthropophagy during times of famine are not exceedingly infrequent, and the history of shipwrecks and sieges, in the horrible truths therein attested, has left nothing for the imagination of poets to invent, when it has told us of mothers taking the lives of their own babes that they might have whereon to satisfy the cravings of their own hunger. Where the

maternal sentiment dies, what noble sentiment can remain?"

Since the above was in type Greely's published statement has appeared. It is proper that his denial of any personal participation in the cannibalism, — much as it may have been justifiable under the circumstances, — should have as wide currency as the original charges: —

"I can but repeat that if there was any cannibalism, and there now seems to be no doubt about it, the man-eating was done in secrecy, and entirely without my knowledge, and contrary to my discipline. I can give no stronger denial. . . . The crew of the Thetis can testify that the body of the last man dead, Schneider, was not mutilated in any way; and the fact that we kept Ellison alive in the hopeless state we were in ought to convince anybody that we are not cannibals, at least not an organized body of cannibals. When I increased poor Ellison's rations, to the detriment of the rest of us, not a man complained, although knowing that it decreased our space of life in a terrible degree. . . .

"For days and weeks I lay on my back unable to move. If, in my enfeebled condition, one or more of my men fed upon human flesh, it was beyond my control, and certainly beyond my knowledge."

For the living it seems to us there would be greater safety in the solitude of the arctic ice, with such a company as the returned explorers, whatever truth there may be in the present "charges" of cannibalism, than in the dullness of summer months in a populous country where newspapers existed and felt the necessity of furnishing daily a new sensation.

MEDICAL NOTES.

— A steamer of the Savannah line which arrived in this city last week brought a large number of watermelons, some three thousand of which were condemned by the Inspector of Provisions and ordered to be dumped into the city scow. A large number of the melons disappeared from the wagons during their transit. The drivers say that these were stolen by boys whom they (the drivers) were unable to keep from plundering the carts. This story looks somewhat improbable in view of the fact that fruit is constantly transported through our streets in wagons without risk of molestation. Moreover, it is claimed that the drivers themselves picked out a number of the best-looking melons and disposed of them to cheap dealers. Numerous cases of illness were reported among boys and others who got possession of the decaying fruit and who ate heartily of it in spite of its bad condition. Opportunity for such evils is favored by the fact that the transportation of condemned fruit is compelled from the owners, the city making no provision for removing it. Under such circumstances there is an obvious temptation to owners and teamsters to redeem something from the loss. In certain cases of disputed ownership fruit has been left to rot on the wharf to the discomfort and even danger of the abuttors, while the authorities were trying to decide whose was the responsibility for the removal. In all such cases it would seem wiser for the removal of condemned fruit to be made by the municipal authorities themselves, the expense if necessary being afterward collected from the owners.

— Sir Erasmus Wilson, LL. D., F. R. S., the well-known and prolific writer on dermatology, and late President of the Royal College of Surgeons of England, died August 8th. He was born in 1809, became a member of the Royal College of Surgeons in 1831, Fellow in 1843, member of the Council in 1870, and President in 1881. He founded the Chair of Dermatology and the Museum of Dermatology in the College of Surgeons in 1869, and was elected the first professor. He made munificent gifts to hospitals, also founded a chair of pathology in the University of Aberdeen. He took a great interest in Egyptology, and it was through his munificence that Cleopatra's Needle was transported from the borders of the Nile and erected on the Thames embankment in London.

— The *Lancet*, in a recent number (July 12, 1884), says: "We understand that Dr. Lyons, M. P., has given notice of an important amendment to be inserted in the Medical Act Amendment Bill, to the effect that two physicians of over twenty years' standing should be made life peers and act as lord justices of appeal in medico-legal trials. Such appointments have been urged by Sir Spencer Wells, Dr. Theodore Williams, and others, and will, if made, considerably strengthen the hands of justice."

—Professor R. Harvey, of Calcutta, advocates the use of the forceps in breech presentations in certain cases (*Indian Medical Gazette*, June, 1884). A number of obstetrical authorities have now declared in favor of this innovation.

— A correspondent of the *Medical Record* (May 17th) who had the opportunity for a number of weeks to make observations on the physical state of the leading female performers in a large circus, writes concerning the influence of their work on the general health, and on the menstrual and child-bearing functions. He found that the riding, jumping, and leaping did not influence pregnancy unfavorably. Temporary suppression of the menstrual fluid sometimes occurs during these exercises, and its duration tends to be prolonged; but an excessive loss was not found in any case. The non-existence of uterine disease could not certainly be ascertained; but it appeared probable, from the absence of pelvic discomfort and leucorrhœa, and from the excellent general health. Their faces did not exhibit any evidence of especial fatigue, and they all ate and slept well. Dr. Post furnishes particulars concerning five of these women: three being foremost riders, and two gymnasts. Their histories differed mainly in the fact that the gymnasts had early abortions without extraordinary cause, while the riders never miscarried, except as the result of a fall, their routine work not producing this effect. The routine life of the gymnast obviously much favors the dislodgment and expulsion of the ovum at an early

stage. But it must be observed that her costume furnishes much less facility for concealing pregnancy, and, therefore, a greater temptation for provoking abortion than is the case with the rider, who can exhibit throughout the eighth month without detection. The fact that pregnant women can undergo the violent exertion they have to sustain while in the ring, and yet bring forth healthy children at term, and suckle them, is most remarkable. The explanation in part lies in their having pursued this habit of life from childhood, the muscular attachments of the uterus being probably rendered unusually firm by the training that has been pursued. Menstruation, however, is more injuriously affected, dysmenorrhœa of some kind being the rule among these women. The menstrual discharge often becomes suppressed during performance, to appear afterwards in excess. The influence of the work on involution of the uterus seems good, for some of these women returned to their occupation in from four to six weeks after confinement, without injury. In some of these women the chest development was very fine, measuring under the clothing thirty-four, thirty-six, and thirty-eight inches in individuals weighing less than one hundred and thirty pounds. With a superb bust curve, in none of them were the breasts large, the effect being obtained by the "ribbing out" of the thorax, which renders even a small breast prominent.

Correspondence.

THE PLASTER-POSTERIOR SPLINT.

MR. EDITOR, — I feel called upon to make a brief reply to the letter of my friend, Dr. Bridgman, in your issue of the 14th ult.

And first let me state that I entirely coincide with Dr. Bridgman in his account of the introduction of the splint, yet as Dr. Gay first became acquainted with the splint through my application of it in the hospital wards, and as we have together taken much interest, not only in studying its indications and application, but also in trying to make it known to the profession at large, is it any wonder that, in a footnote to his valuable paper, he should unwittingly accord to me more credit than belongs to me or than I am willing to accept?

Additional explanation of the passage objected to is found in the fact that up to June, 1882, nothing was known of the new appliance outside of the hospital staff and graduates. At that time, however, on the occasion of the meeting of the Massachusetts Medical Society, Dr. Cushing and myself prepared specimens designed to demonstrate its application, this being, to the best of my knowledge, the first opportunity ever afforded the profession of becoming acquainted with it. I may add that, so far as I am aware, the first published description of the splint is from my pen, and may be found in Mr. Sampson Gamgee's "Treatment of Wounds and Fractures."

I wish, also, to assert my conviction that there does exist a very material difference in point of utility and desirability between the *posterior* splint, as described by Dr. Gay, and the *antero-posterior* splint, as introduced by Dr. Goodhue, and perpetuated by Dr. Bridgman.

Very truly yours,

RUFUS A. KINGMAN, M. D.

BOSTON, *August* 16, 1884.

Miscellany.

VACCINATION AND SYPHILITIC INFECTION.

OUR readers will remember that some two years ago certain experiments were carried out by Dr. Cory, the chief vaccinator attached to the National Vaccine Establishment in England, to test the current belief that vaccine lymph taken from a syphilitic person, if unmixed with the blood of the vaccinifer, does not contain the syphilitic virus, and is hence incapable of imparting syphilis by its inoculation. These experiments could only be carried out on his own person, and with true scientific devotion he set himself to work. The appendix to the report of the medical officer of the Local Government Board for 1882 contains a full account of these experiments. These are summarized in the July number of the *Practitioner*. The paper in which the matter is dealt with was prepared by Drs. Bristowe, Humphry, and Ballard, and Mr. Jonathan Hutchinson. It will be unnecessary for our present purpose to give an account of each experiment; indeed, all but the last one can be passed by with the explanation that children who were obviously syphilitic were selected as the vaccinifers; that in two cases they presented active symptoms of syphilis, and that, notwithstanding this, the ordinary precaution to avoid admixture of blood led to no transmission of the disease in connection with the vaccinations which were effected. The last experiment was performed on July 6, 1881. The vaccinifer was a female infant eighty-four days old. Ten days after birth she began to have "snuffles." When about four weeks of age an eruption appeared upon the arms, and this remained at the time when her lymph was used. There was also a sore upon the right buttock and one in the left nostril. The vesicles which had resulted from the child's vaccination were normal in appearance and not inflamed. The immediate neighborhood of the vesicles was free from eruption. Lymph was carefully taken, and the vaccination was performed in three places, but the operation was unsuccessful and no pock arose. But on the twenty-first day there was at two of the vaccinated places redness and a small papule. These papules grew rapidly. One soon exhibited an ulcer, and at this stage Dr. Humphry and Mr. Jonathan Hutchinson were consulted; both agreed that the spots were syphilitic, and with Mr. Hutchinson's reluctant concurrence they were both excised on the 11th August, the incisions uniting on the following day. But on the 14th one of the places was a little inflamed; on the 17th a gland in the axilla was tender; next day one of the wounds was distinctly inflamed and indurated, and there was a good deal of axillary pain. Towards the end of the month the throat was sore, the glands of the neck were painful, a roseolar rash appeared on the forehead, temples, back of the neck, and below the ears, and anti-syphilitic treatment was fully commenced. Referring to the experiments as carried out by the officer in question, the reporters then sum up as follows: —

"(1.) He has stated to us that the object he had in

view in instituting these experiments upon his own person was to test a current belief that vaccine lymph taken from a syphilitic person, if unmixed with the blood of the vaccinifer, does not contain the syphilitic virus, and is incapable of imparting syphilis by its inoculation. Having acquired syphilis at his last experiment, he had (apart from any question of vaccination) a second object in having the primary lesions excised, namely, to examine microscopically the excised parts, and to ascertain whether the excision would prevent constitutional disease or modify its course. It was further in order to give this second experiment fair scope that he abstained from submitting himself to anti-syphilitic treatment, until the signs of constitutional syphilis had become so clear that doubt of the failure of excision as a preventive measure could no longer be entertained.

"(2.) It is conclusively proved by his experiments that it is possible for syphilis to be communicated in vaccination from a vaccine vesicle on a syphilitic person, notwithstanding that the operation be performed with the utmost care to avoid the admixture with blood.

"(3.) It is to be remarked that the infants from whom he took lymph for his personal vaccination were, in all cases but one, not suffering from hereditary syphilis in a *latent* form, but were infants in whom *active* symptoms were unmistakably present, as shown by cutaneous eruption, snuffles, mucous tubercles, and ulcerations.

"(4.) Moreover, out of the four children thus used, only one was proved to have been capable of imparting syphilis by the lymph taken from its vaccine vesicle.

"(5.) This case is in conformity with general experience in the following respects, among others, namely, that when syphilis is communicated by inoculation the first appearance of the disease is at the seat of inoculation, the taint of the blood being in all cases preceded by a conspicuous, peculiar, and persistent manifestation of disease at the seat of inoculation.

"(6.) The infants from whom he took lymph for his experiments on his own person were in such a condition of obvious syphilitic disease as would certainly have precluded their use as vaccinifers by even an inconsiderate and reckless vaccinator. Indeed, they were selected by him for his self-vaccination because they were unquestionable syphilitic cases. It is a rule of practice in the profession not to use in vaccination lymph taken from a child in whom there is any suspicion whatever of syphilitic taint, or, indeed, in whom there is any skin disease, although of a character known to be harmless; and the observance of this professional rule is strictly enjoined by the Local Government Board in its instructions to public vaccinators through the country."

Perhaps the point of greatest interest in connection with these experiments has reference to their relation to the practice of vaccination as carried out in England. As to this Dr. Buchanan points out that quite apart from the question of the transmission of syphilis by vaccination it has been the practice of English vaccinators to avoid using any syphilitic children as vaccinifers, and the long-continued absence of any authenticated case of syphilization as the result of vaccination in this country led many to doubt whether such a result was ever possible. In order to attain success in the course of experiments to which we have adverted it was necessary deliberately and intentionally to break through an invariable rule of practice which all medical practitioners observe, and to repeat the experiment again and again in the face of repeated failures. So far as public vaccinators are concerned they are bound by the instruction, "Take lymph only from subjects who are in good health, . . . and always carefully examine the subject as to any existing skin disease, and especially as to any signs of hereditary syphilis;" and Dr. Buchanan comes to the conclusion that the observance of this rule offers all the safeguard needed, and that syphilis can only be imparted by a vaccinator in such a manner as no medical practitioner is likely by any accident or carelessness to imitate.

THE TREATMENT OF EPILEPTIFORM NEURALGIA BY NERVE-STRETCHING.

The synonym for this troublesome affection is "incurable facial tic," and in view of former therapeutic measures it seems to be a correct descriptive term. With the exception of the massive doses of opium (ten to thirty grains daily), which alone Trousseau considered of any value among drugs, nothing has been found to give permanent relief. Neurotomy and neurectomy are of only transient effect, but according to some authorities, among them Mr. Walsham,[1] nerve-stretching has given relief, whose permanence is to be inferred from the non-reappearance of pain during the intervals (in some cases long) since the operation. The particulars in some half dozen cases are thus given by Mr. Walsham. He says:—

In the first patient with this disease who came under my care I stretched the infra-orbital nerve. The neuralgia was of ten years' duration, and for two years of this time the patient had been actually bedridden, as the pain was beyond endurance when she attempted to get up. All medical remedies had been tried and failed. The operation was performed in February, 1879. She was completely relieved, and when last heard of, three years afterwards, by my friend, Mr. Anderson, who sent her to me, she expressed herself as having been cured. The second patient, a man thirty-two years old, who had been an out-patient of Dr. Lauder Brunton's, had had the neuralgia for nine years. He had formerly been in good circumstances, but in consequence of his pain had been rendered unfit for any mental exertion, and had gradually lost his business. The neuralgia was confined to the regions supplied by the auriculo-temporal and inferior dental nerves. He had consulted many of the most eminent physicians in London and Paris, and various homœopaths, medical rubbers, and electricians, and had had the inferior dental and mental nerves divided by Messrs. Tomes and Durham. In April, 1883, I stretched the auriculo-temporal nerve, and a week later the inferior dental from within the mouth. The relief from pain was complete; he has had none since, and is now again making headway in his business. The third patient, sixty years old, had suffered for eight years. The pain was confined principally to the inferior dental nerve. I stretched this in May, 1883. Since then he has had no pain except some slight twinges in the infra-orbital nerve (none in the inferior dental) for a few days in March, 1884, ten months subsequent to

[1] Practitioner, July.

the operation, after having got wet through and taken a violent cold whilst following his occupation as a gardener. The fourth patient, a man fifty-six years old, had been in St. Bartholomew's Hospital for some time under the care of Dr. Church, and more lately as an out-patient under Dr. Lauder Brunton, to whom I was indebted for the case. He had suffered for five years. In November, 1883, I stretched the inferior dental and infra-orbital nerves, and he has remained well since. The fifth, a man seventy-three years old, had suffered for ten years with pain, chiefly in the inferior dental. He had had the mental branch cut and stretched, with little or no benefit, at the National Hospital for Epilepsy. In March, 1884, I stretched the inferior dental from within the mouth. The patient, notwithstanding his age, had no bad symptom, and at present has had no return of his neuralgia.

In the sixth case a man, fifty-nine years old, had suffered for upwards of fourteen years. He had been under the care of several physicians, and had had the supra-orbital and infra-orbital stretched on various occasions. Looking to the success of the above cases I attempted to stretch these nerves again, but found, on cutting down upon them, that the tissues were so matted together, as the result of the previous operations, that it was impossible to isolate them. An aneurism needle was passed under the cicatricial tissue in the situation of the nerves, and an endeavor made to stretch it, but it did not yield to any appreciable extent. The pain was as severe after the operation as ever. On more closely questioning him it was found that although he said the pain began in the cheek and darted upwards over the head, it really began in the gums, in the region of the molar teeth, which had been previously extracted, that is, in the posterior dental nerves, and shot upwards towards the back of the orbit. In January, 1883, I removed Meckel's ganglion and the whole of the superior maxillary nerve, after having forcibly stretched its proximal end, from the foramen rotundum to the spot where it emerges on the cheek. The patient had no bad symptom; he slept well the night after the operation, better than he had done for months; he was up and about the ward in a few days, and has had no pain since.

TOXICOLOGY IN LITERATURE.

MR. A. WYNTER BLYTH, writing in the *Medical Times and Gazette* (August 2d), on Old and Modern Poison Lore, speaks of the inaccuracies of dramatists in their literary handling of poisons, and offers a suggestion of a poison suitable for the purposes of the playwright: —

"Few dramatists," he remarks, "have been happy in the description of death by poison; the death of Cleopatra, described by Shakespeare as resulting from the bite of a venomous snake, is like no clinical description of fatal illness from bites of any class of snakes.

"In Philip Massinger's play, The Duke of Milan, Francisco dusts over a plant with a poisonous powder; this plant Eugenia holds; Ludovico Sforza kisses her hand twice, and from this slight contact very rapidly dies — why, it is doubtful whether pure aconitine itself, the most powerful of all known substances, and only separated within the last few years, could be inhaled under these conditions in sufficient quantity to do harm.

"Beverley, in Edward Moore's Gamester, takes poison in the fifth act, after which he makes several pretty long speeches, and ultimately dies suddenly, but, so far as we can learn, with considerable calmness. Nathaniel Lee, in his tragedy, Alexander the Great, provides a poison for the destruction of the emperor, which is described as of 'exalted force.'

> "'. . . mixed with his wine a single drop gives death,
> And sends him howling to the shades below.'

Nevertheless, after taking the poison, Alexander walks about, declaims much, kills Clytus, and goes through the latter part of the fourth act, and most of the fifth, comfortably enough; then raves in delirium, regains his senses, and dies after a very fine speech. There was no poison known to the writers of the plays alluded to which would produce symptoms in any way similar. At the present day there is, however, a liquid made by artificial means, the effects of which are stranger than those imagined by play-writers — after it is swallowed the person walks about for an interval of time varying from a quarter of an hour to two hours. His skin, and even the whites of the eyes, become of a strange, purplish livid color, but he may feel fairly well; then the fatal symptoms set in with appalling suddenness, and he dies in a few minutes. For any one who delights in constructing stories of sensation, these occasional effects of nitro-benzine, just described — the weird blue color, the interval allowing of acts and rhapsodies, and the abrupt termination, afford considerable, although perhaps not commendable, scope."

THE ELIMINATION OF MERCURY DURING AND AFTER ITS CUTANEOUS EMPLOYMENT.

In a reprint from the *Journal of Cutaneous and Venereal Diseases*, vol. i., No. 12, Dr. Schuster, of Aix-la-Chapelle, gives the results of more than one hundred examinations respecting the elimination of mercury in syphilitic patients who were either still under treatment by mercurial inunction, or who had been thus treated for a time varying from one to twelve years. At first, only the urine was tested, by the Ludwig-Fürbringer method, modified by Schridde. Mercury was thus found often in small, but rarely in large quantity, during, and some weeks after, the mercurial treatment. Frequently, however, mercury was not found in the urine. Dr. Schuster, therefore, proceeded to examine the fæces, and found that mercury was always present in them. The result of forty examinations of the fæces was, that mercury was found regularly in relatively large quantity during mercurial inunction. The earliest examination was made ten days after the beginning of treatment. Mercury was found in the fæces for five and a half months after the end of the course, the examination being made at intervals of from ten to fourteen days. Mercury was found in the fæces in all cases in which it was found in the urine; but it was frequently absent from the urine when it was found in the fæces. From this Dr. Schuster draws the following conclusions: — (1.) The elimination of mercury by the fæces is regular and continuous. (2.) The elimination of mercury introduced by a course of inunction of from thirty to forty-five days is completed in six months. (3.) Persistence of mercury in the organism does not occur.

DEATH-PUNISHMENT BY HANGING.

UNDER the head of "Nugæ Hibernicæ," in the *British Medical Journal*, January 5, 1884, are some details of the mechanism of hanging as a death-punishment. Till recently the employment of a short drop, with consequent simple strangulation, led frequently to very painful scenes; but since the employment of the "long drop," fracture of the transverse process of the second cervical vertebra is caused, and instantaneous death takes place by injury to the medulla oblongata.

The drop in Ireland ranged at first from ten feet to seventeen feet, and death was instantaneous. Two cases occurred in which the weight of the criminal was the same, namely, 160 pounds, and the "long drop" the same, namely, fourteen feet; but in one case the transverse processes of the second vertebra were broken across, and in the other case the head was cut off by the rope. A scientific investigation of the ropes followed, and the cutting off of the head was found to be due to deficient elasticity of the rope. These cases led to a full discussion of the whole question, and particular attention was paid to the position of the noose, for which three positions were advocated, namely: (1.) The occipital position. (2.) The subaural position. (3.) The submental position.

(1.) The "occipital knot" had practice in its favor, handed down from the old times of the "short drop;" but experience showed that the "long drop" and "occipital knot" divided all the soft tissues of the neck, except the skin, before the blow reached the second cervical vertebra and medulla oblongata, and there was not sufficient margin of resistance to prevent the head from coming off.

(2.) The "subaural knot" was merely a hangman's ignorant idea, and had no support from anatomy.

(3.) The "submental knot" and "long drop" delivers the first shock on the spine (like killing rabbits by a blow on the back of the neck), and causes immediate death without dividing the soft parts of the neck, which remain to protect the head from coming off.

After the adoption of the "submental knot" the "long drop" was reduced from twelve feet or fourteen feet to eight feet, and the results have proved that an eight-foot drop, with "submental knot," will produce a greater destruction of the transverse processes of the cervical vertebræ than a fourteen-foot drop with the "occipital knot." The transverse processes have been fractured as far down as the fourth vertebra, and death is, of course, instantaneous, and that without risk of taking off the head.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 9, 1884.

Deaths reported 2726 (no reports from New Orleans, Chicago, and Buffalo): under five years of age, 1412; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 903, consumption 280, lung diseases 148, diarrhœal diseases 620, diphtheria and croup 77, whooping-cough 55, typhoid fever 55, malarial fevers 31, measles 28, scarlet fever 17, cerebro-spinal meningitis 10, erysipelas six, puerperal fever three, typhus fever one. From *typhoid fever*, Philadelphia 14, New York nine, Boston, Cincinnati, and Baltimore five each, Brooklyn and Pittsburg three each, St. Louis, District of Columbia, and New Haven two each, Milwaukee, Charleston, Cambridge, Lawrence, and Taunton one each. From *malarial fevers*, New York and St. Louis 10 each, Brooklyn six, Baltimore and Providence two each, Charleston one. From *measles*, New York 19, Pittsburg three, St. Louis and Milwaukee two each, Brooklyn and Taunton one each. From *scarlet fever*, New York seven, St. Louis and Milwaukee two each, Philadelphia, Boston, District of Columbia, Lowell, Lawrence, and Haverhill one each. From *cerebro-spinal meningitis*, New York three, Milwaukee and Springfield two each, Philadelphia, New Haven, and Lowell one each. From *erysipelas*, Philadelphia three, Brooklyn, St. Louis, and District of Columbia one each. From *puerperal fever*, Philadelphia, Milwaukee, and Chelsea one each. From *typhus fever*, Cincinnati one.

One case of small-pox reported in St. Louis.

In 110 cities and towns of Massachusetts, with an estimated population of 1,376,704 (estimated population of the State 1,955,104), the total death-rate for the week was 20.44 against 19.11 and 21.54 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending July 26th, the death-rate was 24.9. Deaths reported 4176: acute diseases of the respiratory organs (London) 159, diarrhœa 881, whooping-cough 118, measles 86, scarlet fever 77, diphtheria 30, fever 33, small-pox (London 17, Liverpool, Sunderland, Hull, and Sheffield one each) 21. The death-rates ranged from 11.1 in Brighton to 33.8 in Leicester; Birmingham 20.6; Blackburn 23.1; Bradford 16.2; Leeds 27.9; Liverpool 31.9; London 25.9; Manchester 27.8; Nottingham 26.9; Sheffield 27.3; Sunderland 24.1. In Edinburgh 18.4; Dublin 28.7; Glasgow 19.3.

For the week ending July 26th, in the Swiss towns, there were 36 deaths from diarrhœal diseases, consumption 28, typhoid fever eight, diphtheria and croup five, puerperal fever two, measles one. The death-rates were, at Geneva 17.3; Zurich 11.8; Basle 19.4; Berne 13.3.

The mereorological record for the week ending August 9th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM AUGUST 9, 1884, TO AUGUST 15, 1884.

BARTHOLF, J. H., captain and assistant surgeon. Relieved from duty at Vancouver Barracks, Wash. Ter., and ordered to take station at Portland, Oregon. Paragraph 1, S. O. 114, headquarters Department of Colorado, August 1, 1884.

HEIZMANN, C. L., captain and assistant surgeon. Ordered to proceed to Fort Ontario, N. Y., and report for duty. Paragraph 3, S. O. 163, headquarters Department of East, August 13, 1884.

KANE, JOHN J., captain and assistant surgeon. Granted leave of absence for one month. Paragraph 1, S. O. 160, headquarters Department of East, August 10, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING AUGUST 16, 1884.

BOGERT, E., medical inspector, to be fleet surgeon, Asiatic Squadron.

BABIN, H. J., surgeon, detached from U. S. S. Minnesota, ordered to Marine Rendezvous, N. Y.

WHITING, R., passed assistant surgeon, detached from Marine Rendezvous, N. Y., ordered to Naval Academy as member of Examining Board.

COOKE, G. H., surgeon, ordered to Naval Academy as member of Examining Board.

RIXEY, P. M., passed assistant surgeon, detached from special duty at Washington, ordered to U. S. S. Lancaster.

WOOLVERTON, T., surgeon, ordered to U. S. S. Minnesota.

DIED. — At Lexington, Mass., August 13, 1884, Abel Bryant Adams, M. D., M. M. S. S., aged seventy-three years.

BOOKS AND PAMPHLETS RECEIVED. — Fifth Annual Report of the State Board of Health of Illinois. 1883.

Streif-Lichter über die Stellung des Arztes in der Gegenwart und sein Verhältniss zur Praxis, etc. Von Dr. Med. Heinr. Schmidt. Berlin.

Twentieth Report of the Trustees of the City Hospital, Boston, with Reports of the Superintendent and Professional Staff, Rules for Admissions and Discharges, Prospectus of Training School for Nurses, etc. 1883–84. Boston.

Second Annual Announcement of the Northwestern Ohio Medical College, Toledo, Ohio. Session of 1884–85.

Transactions Mississippi State Medical Association. West Point, April, 1884.

Puerperal or Childbed Fever. By T. Griswold Comstock, A. M., M. D., St. Louis, Master in Obstetrics, Vienna. (Reprint.) 1884.

Proceedings, Addresses, and Discussions of the Third Semi-Annual Meeting of the Kentucky State Sanitary Council. Held March 26, 27, 1884.

Gun-Shot Wounds of the Small Intestines. By Charles T. Parkes, M. D. Address of the Chairman of the Section on Surgery and Anatomy, American Medical Association. Washington, May, 1884.

Lectures.

ACUTE PARENCHYMATOUS NEPHRITIS.

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL.[1]

BY JAMES TYSON, M. D.,

One of the Physicians to the Hospital, and Professor of General Pathology and Morbid Anatomy in the University of Pennsylvania.

GENTLEMEN, — I have the opportunity to-day of showing you a form of Bright's disease which is not often met with in adults even in the wards of a large general hospital. I refer to acute parenchymatous nephritis. This form of Bright's disease is, as you know, frequently seen in children after scarlet fever and diphtheria, and is also known as acute nephritis, acute croupous nephritis, acute tubal nephritis, and acute catarrhal or desquamative nephritis.

The patient has given us the following history: He is seventy-five years old, and was admitted on December 4, 1883, eleven days ago. He states that his father died in middle life, he thinks from intemperance. His mother died at an advanced age. He had smallpox when a boy, and at the age of twenty-one had what he says was typhus fever. He has never had syphilis or gonorrhœa. He is a gardener by occupation, but has lately worked in a stove store. Up to December 1st, he was in sound health. He recalls no dropsy or other allied symptom previous to this time. At the time mentioned, he began to have headache, pain in the back, and noticed that his scrotum was swollen. He believes that the amount of urine was increased, and he had to get up twice at night to micturate. It must be remembered, however, that this is a common symptom in old men in good health. On admission the feet, legs, abdomen, and scrotum were œdematous, and there was also œdema of the lungs. He appeared to be remarkably strong and active for the amount of dropsy present. There were no effusions into the serous cavities.

Such being the history, let us study the present condition.

The dropsy has almost entirely disappeared. This is interesting as showing the remarkable quickness with which dropsy will sometimes disappear in renal cases. This is a characteristic of some cases of acute parenchymatous nephritis as distinguished from the chronic form of the disease. In seven days the dropsy has almost entirely gone. Our attention being attracted by the symptoms which I have mentioned, the next step was, of course, the examination of the urine. This was found to present an appearance very much like the specimen which I now show you. It was of a smoky hue, and its specific gravity was high, and it contained a considerable quantity of albumen. To-day the quantity of albumen is not so large, not nearly so large as we have in many cases of acute Bright's disease or in some of the chronic forms. On standing, a deposit occurs, and on microscopical examination it is found to consist of large numbers of epithelial casts, of hyaline casts, of blood casts, and of free blood corpuscles. The smoke hue is due to the presence of the blood, which, when present in moderate quantity, always imparts such a hue to an acid urine.

It is not necessary after what I have said in previous lectures to discuss the formation of casts. I shall simply say that epithelial casts are due to a coagulable exudation from the blood, which, after it has been thrown out into the uriniferous tubules, entangles in its coagulation detached or partially loosened epithelial cells. In consequence of the inflammation in the tubules the epithelial cells are loosened from their attachment, and as the fibrinous material contracts it drops out, carrying with it the epithelium. This epithelium is not normal; it is granular, and in some cases highly so. At the same time it has not reached the stage of fatty metamorphosis. It is rather in a state of "cloudy swelling." The blood casts are formed in a similar manner. The blood escapes into the Malpighian capsules, trickles down into the tubules, and the corpuscles become attached to the fibrinous material before mentioned, or the blood itself coagulates, forming the blood cast. Hyaline casts consist of the pure fibrinous material without blood or epithelial cells attached to it. They are formed in tubules in which the epithelium is still firmly adherent to the basement membrane or is altogether absent. In health the epithelium of the kidney is very firmly attached. This is a characteristic of renal epithelium, and in this respect it differs from almost all other forms of epithelium. The epithelium of the skin of the mouth and of all portions of the genito-urinary tract, excepting the kidneys, is constantly exfoliated. It is rare to have the epithelium of the healthy kidney thrown off, and such a thing as an epithelial cast from the healthy kidney does not occur. If the fibrinous material is thrown out into a tubule, the epithelium of which is perfectly healthy, the cast will escape leaving the epithelium behind, but if the epithelium is diseased and loosely attached an epithelial cast will result in this coagulating and entangling process. A hyaline cast has less significance than other forms of casts, because it is produced by slighter derangements of circulation in the kidney. Although hyaline casts do not appear in normal urine yet they may be produced by slight congestions. The hyaline casts which occur in the acute form of the disease are of small diameter, being the diameter of the tubule less the thickness of the epithelium. In chronic Bright's disease hyaline casts of large diameter are found, being produced by the exudation of fibrinous material into tubes which are bereft of their epithelium.

These are the points on which we base our opinion: In the first place the short duration of the case. This, taken in connection with the results of the examination of the urine, — the large amount of albumen, the presence of epithelial and blood casts with free blood corpuscles, serve to establish the diagnosis. Epithelial casts in which the epithelial cells are so slightly changed are never found in the chronic forms of the disease. Blood casts are only found in acute cases. Blood corpuscles are occasionally found in chronic cases, but much more frequently in acute. In the acute stage of Bright's disease the urine is generally of high specific gravity. This is due to two causes: The urine is diminished in amount, and given a normal amount of solids the specific gravity would, of course, be high. The solids are rarely diminished during the earliest stage, but as the case progresses they decrease, and all secretion may even be suppressed. The second factor which contributes to the high specific gravity is the admixture of blood, which sometimes appears in considerable quantities.

What is acute parenchymatous nephritis? It is an

[1] Reported by William H. Morrison, M. D.

acute inflammation which starts in the uriniferous tubules, or, rather, in the cells lining them. I do not say that the process continues in the tubules during the whole course of the disease, or how long it remains there. As stated, other terms are applied to this form of Bright's disease. A good one is tubular or tubal nephritis, because it tells precisely where the disease is located. Parenchymatous nephritis is rather the favorite term to-day, and is also a proper one, as indicating the seat of the inflammation, for, as you know, the parenchyma of an organ is its proper secreting structure. Another term is desquamative nephritis, which has its reason in the fact I have already mentioned, that the epithelium is disposed to desquamate and drop out. The term simple acute nephritis is also applied to this form of renal disease. We usually make but one form of acute nephritis, and that is tubular nephritis. It may, however, occasionally happen that we have a diffuse acute nephritis, that is, an inflammation of the kidney, in which not only are the tubules affected, but the sparse connective tissue between them as well.

What are the changes which take place in the tubules in this disease? They consist primarily in overgrowth and proliferation of the epithelium, and subsequently in its death and desquamation. Before proliferating, the cells enlarge; they become cloudy and granular, and more or less encroach upon the lumen of the tubules. This encroachment is further favored by proliferation of the cells, and it may go so far as to produce suppression of urine in those cases in which the inflammation is very general. Fortunately it rarely happens that all the tubules are affected at the same time. In consequence of this proliferation of cells and blocking up of the tubules the latter occupy more space, and the entire organ is enlarged, and it is particularly the cortex which is the seat of this enlargement. Instead of being a quarter of an inch or less in width the cortex measures sometimes half an inch. The enlargement of the kidney is, therefore, dependent upon the distention of these tubules, yards of which are closely packed in the kidney. If a section is made of the organ it will be found that the cut surface drips with blood, but on scraping the cortex with a scalpel it will be seen that it does not present a red color like blood, but that it is grayish or pinkish-gray in hue. This is in part due to the fact that the blood has been squeezed from the minute capillaries by the over-distended tubules, and in part to the change which has taken place in the cells, causing them to assume a gray color, so that the acutely inflamed kidney, while it contains a great deal of blood, wants one of the classic symptoms of inflammation, that is, redness. In chronic parenchymatous nephritis the kidney is white, because most of the cells have undergone complete fatty degeneration.

If the disease lasts long enough the connective tissue becomes involved in the inflammatory process, and we then have a diffuse nephritis. This connective tissue, which is present only in small amount in health, is capable of undergoing rapid overgrowth when inflamed. Chronic parenchymatous nephritis is, strictly speaking, a diffuse nephritis, because there has been superadded to the tubular inflammation an involvement and overgrowth of the connective tissue.

Acute parenchymatous nephritis is one of the easiest diseases to diagnose if the physician understands the use of the microscope, and to make an accurate diagnosis this is absolutely necessary. I need not repeat the distinctive points I have already mentioned, but an interesting fact which I did not mention is that in nearly all cases of acute Bright's disease the urine contains crystals of uric acid.

Next, as to *treatment*. Many cases of acute Bright's disease, if recognized early, require no treatment but rest in bed and an easily assimilable diet, of which the best form is milk. Although this is true, it does not do to leave these patients unwatched, for the course of the disease is uncertain. And, as a rule, you will not rest satisfied with this treatment, although what more is done will depend to a great degree upon the urgency of the symptoms. We wish to keep the kidneys acting in order to prevent the retention of urea in the blood and the consequent danger to life which arises from this accumulation. After instituting the general treatment which I have suggested, I see that the bowels are opened, for neither digitalis or any other diuretic will act as long as the bowels are constipated. If there is costiveness, some saline laxative, as magnesia or the citrate of magnesia or some of the natural aperient waters, should be given. After the bowels have been opened, digitalis may be given either in the form of the tincture or infusion, giving fifteen drops of the former, or a dessert-spoonful of the latter, every three or four hours. If this does not produce the desired effect, I should not increase the dose of digitalis, for it is liable to derange the stomach, but I should associate with it one of the vegetable alkalies, as the acetate or the citrate of potassium.

When admitted this man was given one tenth of a grain of elaterium to act upon the bowels, and afterwards received fifteen grains of acetate of potassium and a teaspoonful of the infusion of digitalis every three hours, making four or five doses in the course of the day. Under this treatment he did very well and the œdema rapidly disappeared.

If the treatment which I have suggested does not produce satisfactory results and the symptoms grow worse, I sometimes use cups over the loins, relieving the renal arteries through the lumbar arteries, by the anastomosis which exists between them. After the cupping, I usually apply a corn-meal or flaxseed-meal poultice, the surface of which has been sprinkled with mustard. This keeps up a permanent counter-irritation, and it often starts the secretion of urine.

If these measures fail, free action by the skin should be promoted. This is best accomplished by jaborandi, and in this case it became necessary to administer this remedy. As I have said, the patient at first did well on the use of digitalis and the acetate of potassium, but day before yesterday the resident physician found him delirious and acting in a very singular manner. On investigation it was found that although the urine was not actually suppressed he was passing a very small amount. We at once concluded that his symptoms were uræmic and due to the retention of urea and its allies. This complication is frequently met with: a patient will be doing well, when suddenly there will appear coma, convulsions, or delirium as we had in this patient. In addition to delirium the man had slight convulsive seizures. We at once proceeded to treat him as we usually treat such cases in the hospital. An infusion of two drachms of jaborandi leaves in four ounces of water was made, and the whole quantity given by enema. We often make the infusion

with only one drachm of jaborandi, but as the symptoms were urgent a double quantity was used. This did not produce perspiration, and in an hour the injection was repeated. In a short time he sweat profusely. He was also given one drop of croton oil, which acted promptly. The next morning all the symptoms had disappeared and the man was entirely rational. We are not always so successful in removing the uræmic symptoms, but frequently the result is all that could be desired. In this case the dropsy was also greatly relieved by the sweating.

The above well illustrates the usual course which is to be pursued in cases of acute Bright's disease. If the disease is promptly recognized and properly treated from the beginning, the patient generally gets well, but if overlooked, as it often is, the opportune moment may be lost never to be regained. Perhaps no disease demands for its prompt recognition and treatment a broader and more thorough medical education.

There are modifications of the treatment I have described which are demanded by circumstances. In private practice, instead of giving jaborandi I should use the alkaloid, pilocarpin, giving the nitrate or muriate subcutaneously. The dose is from one fourth to one half a grain as the urgency of the symptoms may demand. My usual custom is to give one fourth or one third of a grain, and if sweating does not come on within half an hour I repeat the dose. Jaborandi not only produces sweating, but it also increases the secretion of saliva and may induce purging. It is also a diuretic. We have in this remedy a most valuable addition to the therapeutics of Bright's disease. In order to keep up the diaphoretic action pilocarpin may be continued in doses of one tenth of a grain. This is readily done by the use of gelatine coated pills. One pill may be given in the evening, or one may be given night and morning. The system rapidly becomes habituated to the use of jaborandi and the dose has to be increased. Another good way of administering this drug is to use the inspissated juice by suppository. The fluid extract may of course be used by the mouth, but it is a less agreeable remedy.

If jaborandi cannot be procured, there are other ways of inducing sweating which we have now almost entirely given up, although they are very efficient. Hot-air or steam baths may be used for this purpose. In employing the hot-air bath the patient is covered with a rubber blanket, and a tube with an expanded extremity which is held over a spirit lamp is passed beneath the covering. In the steam bath the steam from an ordinary tea-kettle may be conducted through a piece of rubber tubing under the bed clothing. These methods are not as promptly effectual as the administration of jaborandi, but at the same time there are circumstances when they may be required.

There is another method of treating urgent uræmic symptoms which should be mentioned, that is, bleeding. I should not hesitate to bleed a patient suffering with uræmia if he is not relieved by the measures described. As you are aware the uræmic symptoms are dependent upon the retention of urea and allied substances in the blood, which when they have accumulated to a sufficient quantity, act upon the nervous system, producing delirium and convulsions, or coma. The condition is, in fact, an intoxication. If under such circumstances the patient is bled and a pint or a quart of this blood removed, some of the poisonous material is taken away and the patient is relieved. In puerperal cases I believe that bleeding relieves not only by diminishing the vascular and nervous tension, but by removing the accumulated uræmic poison which has produced the symptoms.

Another valuable remedy for the control of uræmic convulsions, which should not be forgotten, is chloral. So far as the relief of the convulsions go, jaborandi is a slowly acting remedy, because it operates by removing the poison from the blood. Something is needed to act upon the nerve centres and obtund them and make them less susceptible to the poisonous substance. Chloral often admirably answers this purpose. It may be given by the mouth or rectum. By enema the dose is one drachm. I have seen the convulsions stop almost instantly after such an injection.

There is still another remedy which has been strongly urged by some, which should be used with caution, and that is morphia. It is some years now since Dr. Loomis, of New York city, advocated the hypodermic administration of one half a grain of morphia for the relief of the convulsions in acute Bright's disease. There is no doubt that in certain chronic forms of the disease, more particularly in the contracted kidney, the effect of opium is to increase the danger of uræmia; and Dr. Loomis states explicitly that this treatment is only applicable to the acute disease. I confess to being less particular in the use of opium in chronic Bright's disease than I used to be, always excepting contracted kidney, and where other remedies fail I would use a hypodermic injection of morphia in the uræmic convulsions of Bright's disease, but I should arrange the order of remedies rather as follows: jaborandi, chloral, bleeding, morphia.

With such measures these cases can often be brought to a satisfactory termination; and although the appearance of uræmia is a serious sign, yet it does not necessarily follow that the patient will die, and recovery therefrom in acute cases is not uncommon. Uræmic convulsions in chronic Bright's disease is a far more serious condition.

A CASE OF MULTIPLE CALCULI IN THE BLADDER.

BY A. T. CABOT, M. D.

This case owes its interest mainly to the character of the calculi removed, and the clinical history is therefore given but briefly. It is as follows: —

S. R. U., aged sixty-five, entered the Massachusetts General Hospital May 4, 1883, with the following history: The patient has had some difficulty in passing water since 1875. In the year 1880 he began to suffer from frequent micturition, with pain before and during the act. He has sometimes since then had a sudden stoppage when passing a full stream. Riding causes pain.

At present he cannot pass water without the aid of a catheter, and examination shows the prostate to be decidedly enlarged. On the day of entrance Dr. Bigelow examined him under ether, and, finding a stone, proceeded to crush and pump it out. The stone was soft, and broke readily. The lithotrite was introduced but twice. The fragments removed weighed ninety-six grains after they were dry.

On the following day the patient was comfortable, had had no rise of temperature, and was allowed to go home.

Twelve days after he left the hospital I saw Mr. U. by Dr. Bigelow's request. He was troubled at this time with considerable pain in the bladder and rectum. This was worst when the bladder was full and just after emptying it. The urine was extremely foul, and contained a considerable amount of pus. It was drawn with a soft rubber catheter once in four hours. The existence of large inflamed piles made it doubtful how much of the pain was due to the bladder. Thorough irrigation of the bladder improved the character of the water and somewhat mitigated the pain.

In July Mr. U. again entered the hospital, and I removed the hæmorrhoids, which had proved very annoying, with the actual cautery. During this stay in the hospital the irrigation was thoroughly carried out, with the result of a great improvement in the character of the urine.

July 24th he returned home, the pain having almost disappeared. Although he continued the irrigation, at which he was now quite expert, still the pain soon began to return, and assumed a peculiarly sharp character, which he described as like the pricking of pins, and referred to the penis and rectum. A passage of fæces or wind from the bowels greatly aggravated this pain. The urine now became gradually more purulent, and the pus assumed a thick, ropy consistency.

In September I sounded him carefully, without ether, and although I thought for one moment that I got a slight grating sensation, yet with the greatest perseverance I was unable to reproduce it.

In November the catheter drew out for the first time a little calculus about the size of a canary seed, and now almost every use of the catheter produced one or two of these little stones.

Lithotripsy was at once advised, and Dr. Bigelow kindly lent his apparatus for this operation.

November 17th, I operated with the assistance of Dr. Post and Mr. Reynolds. The urethra was quite capacious, and with a No. 28 French straight tube a large number of small and moderate sized calculi were quickly pumped out. There being a constant clicking of larger stones unable to pass through the tube, a small lithotrite was introduced, and several stones were seized and crushed, the largest measuring about three quarters of an inch in diameter. After this débris was removed, one calculus of the size of a large bean persistently eluded the lithotrite, but finally caught in the eye of a No. 31 French tube, and was drawn out. The bladder was then found to be clear.

The patient had no rise of temperature after this operation, and the pain which had been so annoying entirely disappeared. The urine quickly cleared up, a few minute calculi subsequently passing with the water, and complete health was regained, with the exception of the fact that the obstruction in the prostate continued to require the constant use of a catheter.

The calculi removed at this last operation present peculiarities of shape which are quite singular, and which I will try to describe. They are about two hundred and twenty in number, and weigh two hundred and seventy grains. In size they vary from that of a mustard seed to one having a diameter of three fourths of an inch. The smallest are of a regular oval or rounded shape, but all of them that have acquired the size of a large grain of wheat or upwards have a little sharp spine or projection upon one side. This appearance can best be shown upon those calculi which have attained the size of a large bean. Those figured, chosen at random, present pretty well the characteristics of all. They are oval, flattened in shape, and the spines

are situated near the middle of one of the flat sides. Occasionally the spine is upon the edge of a stone, and more rarely there are two or more spines upon one of the sides. A careful search among the whole number of calculi shows but one instance in which spines occur upon both sides of a stone. In a few cases, instead of a spine, a delicate ridge is seen running the whole length of one of the flat sides. The smaller calculi are brown in color, while the larger ones are covered with a whitish layer.

A section through several of the larger stones shows them to be made up of a dark nucleus exactly comparable in size and color with the smaller stones. Outside of this is a crust somewhat lighter in color than the nucleus, and this is covered on the surface more or less completely by the thick whitish layer already described. The line of section being carried, in one or two instances, directly through the spine, it is seen that the outer crust is much thicker on that side than on the other, and that the spine itself is formed almost wholly of this outer crust, although the darker nucleus sometimes sends a slight projection into it.

An analysis, kindly made by Prof. E. S. Wood, shows the inner, darker portion to be composed almost exclusively of calcic phosphate, with a little calcic carbonate, and a trace of triple phosphate, while the outer crust consists chiefly of calcic phosphate, with considerable calcic carbonate, triple phosphate, and ammonic urate.

Professor Wood pointed out the fact that there is generally a somewhat polished look, with indistinctly marked facets upon the spinous side of each of the larger calculi. Upon these facets the darker portion of the calculus shows through the thin, whitish layer which covers the rest of the surface. Many of the smaller stones are also seen by close examination to be indistinctly faceted.

The presence of these spines on a number of the calculi would of itself be a curious fact, and would suggest a special method of formation, but they acquire a much greater interest when it is considered that every calculus which has attained a moderate size is provided with one or more of them. In short, that all of the larger calculi have been exposed to some influence which has compelled them, almost without exception, to assume this peculiar form. The explanation of this is not easy.

The theory advanced by Professor Wood seems more plausible than any other which has been suggested or has occurred to me. His supposition is that the calculi lay in some part of the bladder where they were not much stirred about, possibly in a sac or pocket, and that they were enveloped in mucus which held them in a pretty constant relative position. Under these circumstances the fermentation and consequent deposition of salts would go on very actively in this stagnant mass, and the spines would be accounted for by the projection of parts of certain calculi into

the interstices of the mass and the rapid deposition of salts upon these portions.

The facets about the spines would be caused by the friction of the calculi between which the spines projected. The occasional appearance of a ridge with facets on each side of it strengthens this view.

The points which at first sight are not sufficiently explained by this theory are: *firstly*, the fact that each and every one of the larger calculi possesses a spine; *secondly*, that this spine is almost invariably situated at or near the middle of one of its flat sides; and, *thirdly*, that in but one instance are there spines upon opposite sides of a stone. This latter seems an almost insuperable objection, for it would naturally appear that the calculus lying in the midst of the mass would possess spines projecting in various directions into the interstices about it.

These inconsistencies are explained, however, if we consider that the smaller calculi which are found to be evenly rounded or faceted on several sides occupied the centre and lower part of this mass, and that the larger calculi lay upon the surface.

That the mass of calculi does tend to take on this arrangement can be demonstrated by gently turning them about for some time in a bag or bottle.

If we once accept the probability that the calculi were thus arranged in the bladder, it can be readily understood that each of the larger calculi lying upon the surface would have one or more spines or ridges projecting into the interstices of the underlying mass, and these spines would naturally occur on one of the flat sides upon which the calculus would necessarily rest.

That the spines do not occur on opposite sides of any of the calculi shows that there was so little motion among them (owing largely, no doubt, to the enveloping mucus) that they did not often turn over and present what had been the free side to the action of the mass of other calculi.

The greater thickness of the outer crust on the spinous side as compared with the smoother side, which was exposed to the action of the urine and friction of the bladder wall, shows the greater rapidity of deposition upon the side buried in the stagnant mass, and is one of the many bits of confirmatory evidence which go to support the explanation which I have endeavored to give of this most singular phenomenon.

While this paper was awaiting publication, Mr. U., after four or five months of perfect ease, had a recurrence of his cystitis and a return of pain which caused him again to apply for advice. A sound revealing the presence of a stone, he was etherized July 24, 1884, and one hundred and twenty-seven grains of calculous matter were removed. The greater part of this was contained in a soft phosphatic stone about the size of a hickory nut.

There were, besides, about a dozen calculi, each of the size of a bean, and resembling in consistency those removed at the previous operation, but differing from them in the absence of the regular projections. One or two of them only posseesed little protuberances, distributed irregularly over their surface and of insignificant size.

Their small number, making mutual attrition less close, prevented, no doubt, the molding which shaped their predecessors.

THE ADVANTAGES OF MASSAGE IN RHEUMATIC GOUT.[1]

BY DOUGLAS GRAHAM, M. D., BOSTON, MASS.

"I' ll knead him; I 'll make him supple." — SHAKESPEARE.

RHEUMATIC gout, rheumatoid arthritis, or arthritis deformans is too familiar to us all to need any lengthened description. We readily distinguish it in most cases by its slow and progressive character; by its chronic or subacute course with frequent exacerbations and remissions; by its spreading symmetrically from the small joints to the larger, usually in the upper extremities first; by the thickening, permanent enlargement and often deformity it occasions; by its never affecting the heart and not being hereditary; and by its attacking females oftener than males. The term rheumatism is often used to cover a multitude of diseases, as charity is to cover a multitude of sins, and when rheumatism assumes a chronic form after an acute attack it may be impossible to see any difference between this and rheumatic gout. Recent views regard arthritis deformans and kindred disorders as possibly of nervous origin. This might seem to be the case when the malady begins with a quiet pulse and clean tongue, and when the patient complains of languor, loss of appetite, pain and stiffness in the joints, and perversion of nutrition. But as to causation, the ground may be easily covered by saying that whatever deteriorates the system, whether by mind or body, in those predisposed to this or any other disease, may, and probably will, precipitate its onset.

It is to be regretted that our success in the treatment of this obstinate affection is not equal to our knowledge of its pathology. An ounce of relief or an extra inch of motion is worth infinitely more to patients and physicians than a foolscap of such information as that the disease is a panarthritis involving cartilage, bone, and synovial membrane; ligaments, tendons, and bursæ, with thickening of the bones and thinning of the cartilages. With strange inconsistence Professor Senator, of Berlin, in his treatise on Diseases of the Locomotive Organs, describes this malady as usually selecting joints which are most continuously and severely overtasked by sewing, knitting, watchmaking, and the like, while on another page he tells us that the thumb is generally spared and remains freely movable. For such a description he may be credited for drawing upon his imagination rather than from observation. I am sure we all know that the freedom of motion is longest preserved in those fingers which are used the most: first, in the index, second in the middle finger, while the thumb shows greater signs of being affected, and the ring and little fingers are generally worst of all. Moreover, Senator's description is again at variance with the only remedial course, of which he speaks in unequivocal terms by saying: "It is important in all the forms of this disease to maintain the functional activity of the affected joints as far as possible by means of active and passive movements. Absolute rest promotes stiffness of the joints, fixes the limbs, and atrophies the muscles." If his first statement were correct, then the treatment he so strongly recommends would be veritable homœopathy: disease produced by motion relieved by motion. But unfortunately this is not so, at least with

[1] Prepared for the Section of Practice of Medicine of the American Medical Association.

regard to dosage, for in using massage and passive motion in these cases long and frequent visits and arduous work are necessary; but in my experience they amply repay both patient and physician for time and trouble expended. Led on by gradual improvement from the use of massage in five out of six cases of well-marked rheumatic gout, I kept up this treatment until unlooked for results were obtained, so that four of these cases regained tolerable use of the affected limbs, and in one recovery seemed to take place.

Berghman and Helleday report three cases, Cronfeld one case, and Balfum, of Edinburgh, two cases of rheumatic gout treated by massage and movements with results similar to those I have obtained, and only one of them had a disappointing relapse. The mode of procedure in my cases was deep manipulation without friction or inunction, passive motion, as far as pain would allow and sometimes farther, and resistive motion as soon as it could be done, the details of which I have described more fully elsewhere. If pain disappears soon after it is caused by any of these operations it may be disregarded; if it lasts for several hours and increases after subsequent efforts, they must be suspended. Kneading with one hand so as to break up indurations or disperse effusions, while the other hand pushes along the circulation in the veins and lymphatics above the joint, is often a good procedure, and quickly leads to the absorption of products not too firmly organized. Blisters and powerful derivatives in the neighborhood of joints affected with rheumatoid arthritis are considered more likely to promote than to retard the affection, according to the studies of Senator. Massage of the adjacent skin and muscles acts as a physiological derivative and raises nutrition to a high degree by a rapid interchange of materials, owing to the force and speed of the circulation being increased and obstructed lymphatics and capillaries made permeable. In this manner the soft structures may be made to adapt themselves to nodosities and deformities that cannot be removed.

When the disease is very active, or the muscles fattily degenerated, the tendons frayed out and thinned and loose cartilages in the articular folds of the fibrous membrane, or when bony anchylosis has taken place we should not expect anything from massage.

All of my cases had been well nigh rubbed to death in the ordinary way, besides having exhausted the resources of the materia medica, baths, and mineral springs of all kinds, electricity, etc., before coming to me for massage.

CASE I. Miss A. was sent to me by Professor Da Costa, of Philadelphia, in 1873. She was then seventy-eight years of age, and had been bedridden for eight months with rheumatic gout. The disease had affected every joint of her limbs and apparently had run its course and done its worst. There was eburnation of the articular surfaces and rattling of the bones, with distortions of almost every joint. There was neither anchylosis nor contracture, but only slight indolent thickening around the joints with great muscular weakness. The patient was nervous and depressed. Pulse 92, and dicrotic. After one application of massage she could put her arms under the bed clothes and pull them up around her neck. Four days afterwards, having had daily massage, she could reach back so far as to get an object behind the pillow on which her head rested, sleep was better, and she was greatly soothed by the manipulation. In seven days her pulse was down to 79, and steadier, and she walked across the room half supported. The following day she fed herself for the first time since her illness. In three weeks she could walk twice the length of her room with slight support. It seemed cruel to ask this patient to walk, so badly were her ankles deformed. But there was no pain; the sensitive structures of the joints were probably destroyed. This patient had massage twenty-three times in one month, and the use of her limbs and general condition were greatly improved. I fancy there may have been times during her illness when massage would not have been of much use to her. She was the most delicate of a family of six, having suffered from pleurisy, pneumonia, hæmorrhages from the lungs, etc., and she outlived them all.

CASE II. Mr. S., about fifty years of age, was sent to me by Dr. Thomas G. Morton, who had clearly explained to him the nature of his affection and told him that benefit might result from a long course of massage. For a year the patient had suffered from periarticular thickening of the finger and wrist-joints of a semi-solid nature, less of the elbows, ankles, and knees, in all of which places there were frequent but not severe attacks of pain of a non-inflammatory character. His general health had greatly deteriorated, sleep was poor, appetite small, and he had lost flesh, but still he could go out every day and attend to some business. Daily massage was used for a while, afterwards every other day. Improvement was slow and almost imperceptible. At the end of ten weeks the periarticular indurations had decreased, the joints were more comfortable and more flexible, sleep and appetite had improved, and the patient had gained flesh. At the end of four months massage was discontinued, the patient being to all intents and purposes well, having regained his natural sleep and appetite and increased in weight to a marked degree. The circumference of his wrists with the improved nutrition being the same as when the induration was present. There was still slight enlargement of some of the phalangeal joints, but the patient could shut his hands firmly, whereas at first they could only be semi-flexed. He said if he thought he could have been cured in this way he would not have sold his house and business with the expectation of going to Europe to seek for relief.

CASE III. Mrs. A. G., thirty years of age, enjoyed good health until she was nineteen years old, when rheumatic gout appeared first by swelling and pain in the last joint of the left thumb, and soon the other joints of both hands and fingers were similarly affected. Four months later the ankles became swollen. Then there was a respite for a year, and at the end of this time there was another exacerbation for five weeks. Six months later it was apparent that the hands and feet were "growing out of shape." About this time she became pregnant, and the disease was in abeyance during this state, but after the child was born the joints were generally affected as before. Again there was a year of improvement, followed by grief and taking cold, which caused a relapse, and in 1877 she walked with great difficulty. Then iodide of potash, arsenic, a sojourn at Caledonia Springs, and electricity were tried, but the patient grew worse. In the summer of 1881 Dr. Goodrich, of Bakersfield, Vt., rubbed the knee joints very hard and hurt the patient a good deal, but she improved so that she could walk with a cane and go up and down

stairs, though the legs were greatly bent. She relapsed again in a few weeks.

This patient came to me in February, 1882, with knees flexed to almost a right angle. There was slight effusion in them, and dry creaking on motion. There was thickening around the ankle-joints, though the motion was free and strong. Hip-joints not affected. The ring and little fingers of both hands were hopelessly deformed, the first row of phalanges being extended far back, the second and third sharply flexed and anchylosed. The thumbs, fore, and middle fingers were somewhat out of shape, but remarkably good use of them was retained. The left wrist was strongly flexed, the elbows and shoulders comparatively free, though they had been severely affected. The patient was bright and cheerful, and looked healthy, notwithstanding that she was suffering from a general bronchitis and weighed but eighty-two pounds. Her appetite was fair and bowels constipated. A tonic pill to increase the appetite and regulate the bowels was given, and general massage used daily. Her joints were not very sensitive, and from the first the massage was agreeable; the aches and pains disappeared in too remarkable a manner for me to ask anybody to believe. In three weeks she was eating very heartily, and taking five goblets of milk daily, and was free from discomfort; and after vigorous extension of the knees, which hurt at the time, they felt better all day, and we had gained one and one fourth inch extension at the ankle. In two months the menses, which had been absent for eighteen months, returned, and they have continued to return ever since with greater regularity than they ever did before. In three months nutrition had improved to a marked degree. At the end of this time, the patient having been in preparation by a variety of impromptu gradual extension apparatus, I put on each leg long lever splints, which made extension from the heel, and pried down the knees by means of wide bandages above them on the anterior aspect of the thighs, while the short arms of the lever rested on the back of the thighs.[1] These were kept on night and day for twelve days, and during the last seven days of their use the limbs made daily extension. After they had been on for twenty-four hours the patient liked them, and later, when temporarily removed, she felt faint for want of their support. They were then removed for eleven days, and light splints applied, and with these the patient stood up. After six days more of the long splints the legs were about as straight as people's usually are in use. By this time the joints had become sore, and the patient was not sleeping well. Two weeks later the patient walked twice across the room, pushing a chair before her to balance herself; ten days later she did this twenty-two times, and in ten days more she walked without anything for support except light wire ham splints. Four weeks later she was going up and down stairs alone, and two weeks after this she frequently took a walk of half a mile with the aid of an arm and her ham splints. It was then six months from the time treatment was begun, massage having been kept up all this time. At the end of seven months and a half the patient returned to her home, wearing the usual supports for weak knees, but unfortunately when these were unfastened there was not much bend to the legs. This, however, has improved by the patient's efforts. It is now eighteen months since the patient went home, and she has continued to gain in every respect without treatment. The flexed wrist and movable finger joints made good progress under massage.

[1] I first saw this used by Dr. E. H. Bradford.

While I was attending this patient there came to me a report of a somewhat similar case treated in like manner with better results than could have been anticipated, and this inspired us with hope and perseverance.

CASE IV. Dr. Carl Gussenbauer, Professor of Surgery at Prague, gave the massage himself in this case. The patient was a lady, forty years of age, who had suffered from rheumatoid arthritis for twenty-two years. The trouble began in one elbow, and later affected the finger-joints. Rest and local applications were without effect. In the following years all the joints of the body were attacked. During two pregnancies no new joints became affected, and those that had been were more endurable. The malady progressed in spite of medication baths, mineral springs, electricity, etc. The patient had not walked any for eight years. Pains by day and night disturbed her rest, and she had become thin, anæmic, and constipated. The heart's action was irregular, and there were attacks of syncope at times. In this condition Professor Gussenbauer undertook massage with great misgivings. He not only applied massage to the joints, but to the whole body: to the joints for the painful swellings that affected both upper and lower extremities, as well as some of the dorsal and lumbar vertebræ; to the whole body to favor the nutrition of the atrophied muscles. There was but a small range of motion in any of the joints of the limbs, owing to adhesions in them and in the sheaths of the tendons, producing the characteristic contracture, and these he hoped to gradually overcome by passive motion. The deformity of the articular extremities of the bones, of course, could not be removed. He *massëed* the patient daily, and gave her passive and active motion, and after fourteen days he had the pleasure of seeing the swollen joints decreased in size and their motion improved and less painful. At the end of a month the patient could walk about her room with a cane, and the improvement was so great that recovery seemed possible. For the next four months the patient was *massëed* by his assistant, Dr. Schmid. The result was that the pains and swellings of the joints and capsules all disappeared, and they became movable to almost a maximal extent except that of one elbow, which had undergone bony anchylosis. The muscular strength of the patient had increased so that it often tired out the operator to give her the active or resistive movements. She could walk in her garden for fifteen minutes without fatigue. Nutrition improved more and more, the anæmia disappeared, the pulse became regular, and menstruation returned, unaccompanied by fits of prostration, as formerly. *Tapotement*, or percussion with the ulnar border of the hand, with the palm, and with the fist, was freely used in this case.

In several cases of chronic articular rheumatism Professor Gussenbauer reports favorable results from massage.

CASE V. While some patients become thin under rheumatoid arthritis others grow fat. This was the case with Mrs. J. L., fifty-eight years of age, who had suffered with the disease for fifteen years. In seven months under massage she regained free and natural use of her limbs, which she retained until a short time before her death. For the first two years her joints gave her but little trouble, but at the end of this time she was

confined to her bed five months with arms so stiff and painful that when they were out of the bed clothes she could not put them in again alone. Later the trouble left the arms and appeared in other places, but never in the toes. Her history is one of pains and stiffness of joints and muscles, with occasional remissions, the disease all the time slowly progressing. Her condition had been made much more comfortable by alkalies and laxatives prescribed by her physician, Dr. J. P. Oliver, who kindly referred her to me for massage. Previous to her malady she had been very thin and active, but for the last ten years of her illness she had grown very fat and heavy. For the last year her mode of locomotion indoors had been by means of a wheel-chair, and it was with difficulty she could be got in and out of a carriage. On each side of the patella it was evident through the layers of adipose tissue that the capsules of the knee-joints were thickened, and it was to these places the pain of extension was referred, and this was limited to about three fifths its normal range. Flexion was natural, and dry crepitus could be heard and felt on motion. Massage and movements every other day, with the use of curved ham splints, and later straight ones, produced good results. In five weeks she was walking about the house with a crutch and cane, and the legs could be straightened so that the popliteal spaces would touch an applied straight ham splint, and free motion was gained to this extent. The splints proved a support and comfort in walking, and were worn for several weeks longer to overcome the tendency of the posterior femoral muscles to shorten. At the end of three months the patient could walk the length of a room and back again without support of any kind, after getting started by assistance for a few steps. She had then lost the pain in the joints that troubled her by night, and pulling the legs no longer hurt the knees as formerly. When the knees ached, walking relieved them. The indurations and thickening were disappearing, and a hard, painful spot behind the left hip had entirely gone, and the patient could turn easily in bed. In six months the patient walked easily and gracefully without crutch or cane or splint. A month later she got up from her chair alone, and walked as well as any one of her weight could be expected to do, and this improvement continued for six months longer, until an affection of a different kind supervened and suddenly carried her off. I need not say how sorry I was to lose this patient, who did me as much credit as any I ever had. The beneficial change in the knees was an indication of what had taken place in the other joints, in the fingers, wrists, and elbows, thinning of indurations, and increase of motion.

CASE VI. Miss E. P., forty-five years of age, at the change of life, well nourished, and a picture of health, has suffered from rheumatic gout and its variations for five years. During its early appearance, while crossing the Atlantic and returning, all the symptoms disappeared only to return as soon as she landed. Two years after the disease began she was seized with severe gastric disturbance for several months, and during the worst of this the joints were remarkably well. With the disappearance of the stomach trouble the mischief in the joints returned. The patient had derived, and still continues to derive, marked benefit from forty to eighty grains of salicylic acid, given in divided doses during the day with bicarbonate of soda and carbonate of ammonia. This was prescribed by her physician, Dr. Lucy E. Sewall, who kindly referred her to me for massage. As the patient was improving I could see no need of adding this treatment, for cauterization of the knees was having a good effect, and making them feel better all day afterwards. It was agreed, however, to try massage on the worst limb, the right leg. There was a mass of feebly-organized, indolent tissue in front of the condyles, which was easily dispersed, and its absorption hastened by massage, even the first sitting producing a marked effect, so that the adherent skin became free, and the hyperplastic tissue softer. At the end of a week, with daily massage, this semi-indurated tissue had almost entirely disappeared, and the feeling as if the joint were held by an iron band in front of it had correspondingly lessened; the patient could stand more easily, and push the limb against resistance more vigorously; the œdema of the leg and swelling of the ankle, which were partly controlled by a bandage, had also improved. During the first three weeks daily gain was perceptible, and at the end of this time her physician asked me to apply the same treatment to the other leg, which had not been getting along so rapidly under cauterization as the worse one had been under massage. After this they improved *pari passu*. A splint was worn for twenty hours every other day on the right leg, and this was well tolerated, and soon overcame a tendency to bending of the knee. The hands and arms made progress, and in two weeks she could use them more freely, and write more easily. At the end of thirty-nine days, having had daily massage, the patient took a ride, getting in and out of the carriage with an ease that surprised herself. Three weeks before this she could scarcely take a step, and for a year she had not been able to walk in any way worth mentioning. Massage was then used every other evening, and she always slept well after it, but not when it was omitted. Manipulation made her lame and sore for several hours afterwards, only felt, however, on motion. She continued to gain under massage until she went to the country, two months from the time it was begun. She improved for three months while in the country, but on her return to the city she rather lost ground, which massage scarcely made up for. After two months more of this treatment it was suspended for two weeks, and during this interval she suffered from general stiffness, wakefulness, and fullness in the head, all of which disappeared promptly on resuming massage. And now, in spring time, with the most unfavorable weather, and arduous professional duties, the patient is again improving. She has good use of her arms, and the thickening of the knee-joint capsules is decreasing, and she walks pretty well with very little assistance.

CASE VII. Mrs. C. J., fifty-two years of age, has had rheumatoid arthritis for eight years, which has pursued a relentless course in spite of twenty-three physicians and all sorts of treatment. The joints of her hips and back are the only places free from the disease, which at present is pursuing its ravages in all the joints of the upper extremities, having for the present got through with the lower ones. Her general health is good, but before this trouble she was delicate and dyspeptic. Massage every other day for six weeks, though removing the peri-articular swellings and thickenings, and extending the knee-joints a little, which are almost bent at a right angle, has had no other apparent effect except to make the joints lame

and sore, and the patient tired. The upper extremities are almost anchylosed, and resent passive motion. The patient perceives no improvement from the massage. This is the most discouraging case I have yet encountered. After the disease has spent itself on the upper extremities there will probably be a chance for massage to do some good.

By means such as we have been considering, Fuller, of London, has told us that when the contracted tendons seem almost to require the surgeon's knife for their relief operative interference will often be rendered needless. In one case, by persevering for nine months, he straightened a leg that had been flexed for four and a half years. Indications for encouragement he clearly expresses in these words: "When, as is usually the case, the contraction depends upon simple gluing together of the structures external to the joint, with thickening of the capsule, and, possibly, some remains of effusion within the cavity, or into the bursæ external to the joint, I see no reason for despair as to straightening the limb, however long contraction may have existed."

CASE VIII. Rheumatoid arthritis of a single joint, resulting from injury, is recognized. I do not think I have seen more than one case that would agree with this. The knee-joint had been injured ten years before, and there was thickening, grating, slight deformity and shortening, but free motion, though walking was exceedingly limited on account of pain, weakness, and the weight of the patient. She had been rubbed an hour a day for a year by a very nice person, with the result of always being tired after the procedure, and getting no better. Twenty minutes' massage with carefully increasing resistive movements every other day, for two weeks, improved her walking to an enjoyable extent. The induration was lessened, and the comfort of the joint increased.

No description of the effects of massage in rheumatic gout would be complete without reference to the case of old Admiral Henry. In 1810 he was seventy-nine years of age, and had suffered from this affliction for twenty-eight years. There were swellings of his knees, ankles, and insteps, which made him quite a cripple, and his fingers were also swollen and contracted. His stomach and bowels were hard, painful, and disordered. By means of various instruments made of bone polished smooth and hammers covered with cork and leather he persevered in the use of deep friction and percussion, night and morning, for three years. At the end of this time, it is said, he had completely succeeded in removing the swellings, and had restored himself to the use of his limbs. His operations were at first painful, but ceased to be so after a little while, and soon they became so pleasant and useful that after having gone through with them in the morning he felt better all day. At the age of ninety-one he wrote to a friend: "I never was better, and at present am likely to continue so. I step up and down stairs with an ease that surprises myself. My digestion is excellent, and every food agrees with me. I can walk three miles without stopping." This was in 1823, and he may be alive yet for anything I know.

The Admiral's pathology and therapeutics are of interest. He considered the chief cause of disease to be deficiency of circulation, and the best means of correcting this to prevent the nerves and muscles from falling asleep and getting fixed, for which purpose they should be kept loose by instruments worked among them. "By keeping the blood-vessels, nerves, and tendons in constant action by means of these instruments the blood is rendered pure: it passes quickly through the blood-vessels, leaving no *fur* behind it, so that ossification and stiffness are prevented." This quaint remark about the blood leaving no fur behind it is a noteworthy illustration of how a layman may express himself better than he is aware of, or, in common language, "hit the nail on the head." This fur of old Admiral Henry corresponds to what we know of the white blood corpuscles which move along so slowly in the circulation, having a tendency to adhere to the walls of the vessels, and which, when the current is retarded, as in points of inflammation, congregate in vast numbers, and often migrate into the extravascular tissues, thence to be resorbed or become the foci of pathological changes.

MENSTRUATION IN WOMAN AND ANIMALS.

BY ROBERT W. LOVETT, A. B. (HARVARD MEDICAL SCHOOL.)

THE great obscurity which still surrounds the process of menstruation makes it desirable for us to use in the study of it every legitimate means, and it may be that a little wider view of the process may be gained by a study of the function as it exists in the lower animals.

In general there is in plants and animals at the season of reproduction a more or less marked manifestation of increased activity. In plants the analogy might be a trifle strained perhaps, yet their flowering season is of course their season of reproduction. We can hardly expect much analogy to menstruation in animals below the mammalia, but there are the foreshadowings of a periodical sexual activity very low in the scale. Birds, fishes, and reptiles have no uterus, although having of course the genital tracts from which the uterus is later developed. In birds "many acquire bright colors and other decorations in the breeding season alone," and "certain ornamental appendages become enlarged, turgid, and brightly colored during the act of courtship." (Darwin.) At the time of the oviposit fishes show a genital excitement, according to Guersant, their sexual orifice swelling and being clothed with a red tint. In the amphibia the oviducts become lengthened and consequently more coiled at the breeding season. Several lizards secrete especially at the coupling season an odorous, fatty liquid from glands at the inside of the thigh. Snakes also show an increased activity of the anal scent glands in the breeding season. But we must go higher in the scale.

In the mammalia, so far as known, every animal is subject to periods of heat. During this time alone will the female admit the male (with the exception of monkeys), and of course at this time only can conception occur. The time of this rut is determined by the surrounding condition of food and climate, so that the young shall be brought forth at the season of the year most favorable to their growth and early sustenance. Among wild animals, as a rule, conception takes place, pregnancy follows, parturition and lactation are accomplished, and at the next suitable season the rut returns to be again gratified. Wild animals are in heat only once or twice a year. When from the absence of the male or any other reason conception does not take place at this time, it is not known in the case of wild

animals whether the heat returns sooner than it would otherwise have done, but in most of the domesticated animals it returns much sooner than if pregnancy had taken place, and keeps on returning until it is gratified, and this return is in a regular rhythm for each animal, and, so far as known, according to Darwin and Laycock, this return is always in seven days or in a multiple of seven days.

Domestication increases markedly the reproductive powers; puberty not only comes earlier than in the wild state, but also more young are produced. The favorable conditions for the early life of the young is probably the cause of the more frequent return of the heat in the domesticated animals. At this season, in all known animals having a vulvar aperture there is swelling (Wiltshire). Probably there is in all the mammalia at least a mucous flow from the external genitals at these times. The kangaroo, as a representative of the marsupials, has a bloody and odorous flux in April and September. As we go higher the blood is said by Wiltshire to become more prominent in the flow in proportion to the degree of development of the genital organs. At any rate, a more or less bloody flow is established in sows, ewes, bitches, asses, mares, and cows. In the latter Newmann found blood exuding from the internal surface of the uterus in the rut, and it is estimated by others that the cow loses at each period from one to two ounces of blood. The cow is subject to menorrhagia, and two cases are reported by Wiltshire where heifers apparently suffered from hæmatometra. Dalton says that cows are restless and agitated at rutting time, and Mivart says the same of the cat.

Unfortunately, it is impossible to draw any trustworthy conclusions from observations upon the anthropoid apes; when in confinement they are under such highly artificial surroundings that any inferences drawn as to their normal sexual processes must be very misleading. Many species never breed in confinement. Wiltshire states that monkeys at intervals of four weeks have a flow of nearly as pure blood as has the human female. Other authorities speak of a mucous flow from the swollen genitals, and all bear witness to the intensified sexual desire of the females at these periods, most of the females, however, being salacious at all times.

In the animals where the periodicity is known, it bears no relation to the gestation period. The periods which seem well established are as follows: The cow is in heat every three weeks; sheep and sows every two weeks; mares, buffaloes, and zebras every four weeks. Observations on this point are surprisingly few and imperfect. Cruikshank, Raciborski, and Bischoff have proved that ovulation takes place spontaneously at the rut. No one has proved that it does not take place at other times, to be sure, but it seems unlikely, and in sows, at least, single corpora lutea are not found. In any sow's ovary all corpora lutea look of the same age, and the general appearance points rather to the rupture of a number of follicles at once than to ovulation at random.

I am far from offering these scanty and imperfect observations as a proof of the identity of heat and menstruation, but the two bear a very close resemblance in their rhythmical periodicity, their discharge from the external genitals, and their accompanying constitutional disturbance, and therefore it seems hardly reasonable to deny the identity of functions of which we know almost nothing in animals and little enough in the human species. Wiltshire goes so far as to claim that the primitive seasonal influence has not yet died out in woman, as he affirms that she begins her menstrual life oftenest in the summer, and brings forth her offspring most in the spring of the year. The character of menstruation among savage women would be a most interesting link in the chain of evidence, had we observations on the point. Velpeau says that he has heard that women in Lapland and Greenland menstruate only three or four times a year, and Roberton says of Lapland women that the flow is scanty, and that sometimes they only menstruate in summer. But however we may regard the ancestry of menstruation, it exists as a fact, and the consideration of it in the human female presents itself under three heads: its manifestation in the general system, in the ovaries, and in the uterus.

As to the Systemic Manifestation. In some six hundred and twenty cases investigated by Biene de Boismont and Dr. Jacobi, about seventy per cent. suffered pain during menstruation. The cases were taken at random from all classes, and trades, and were healthy women. The recent investigations of Hermann and Uedeler show that among nulliparous women about the same per cent. suffer from dysmenorrhœa, whether their uteri are flexed or straight, and that in the three classes of nulliparous women, namely, those suffering much pain, little pain, and no pain at all, the percentage of flexed uteri is practically the same, all of which seems to show that dysmenorrhœa is a syatemic accompaniment of menstruation in a much larger number of cases than is generally supposed. Jacobi found that the excretion of urea was increased before menstruation, reaching its highest point just before the flow. During the flow it falls below normal and remains below normal for a few days. The temperature is increased before menstruation, during the flow it falls, but not quite to the normal. The arterial tension is highest just before menstruation, and lowest just after it. That is, the woman is in her best estate a few days before each menstruation. A certain degree of lassitude and irritability seems normal to the menstrual epoch in the ideally healthy woman, and such would seem accounted for by the pelvic congestion; but most women suffer pain which is not as yet to be explained by any known process going on in menstruation.

The Manifestation of Menstruation in the Ovaries. The wide-spread theory of the necessary coincidence of the rupture of a Graafian follicle with menstruation was established by analogy with the lower animals and by a few autopsies, where in menstruating women freshly ruptured follicles were found. Beigel says: "The number of cases in which ripe follicles have been found in the ovaries of women who have died during menstruation is extremely small." Bischoff published ten cases in support of this theory, in all of which he knew the time of the last menstruation. In three of these cases the rupture of a follicle had not taken place at the last menstruation, and in two of the others there was present with the corpus luteum of the last menstruation a freshly ruptured follicle, which two events could not have been more than three weeks apart. He then says, "The results here obtained show that in the human female at each menstrual period, a Graafian follicle is ripened, swells, and usually bursts," a conclusion which seems hardly warranted by the cases.

Williams gives a series of sixteen cases. In six of these menstruation had been going on for four days at the time of death, and in only two of these six did he find a freshly ruptured follicle. Ashwell examined the ovaries of three women who had died during menstruation, and in no one of them was a ruptured follicle found. There are plenty of similar observations, but the recent work of Leopold on the subject is by far the most worthy of consideration.

He took into account only the fresh ovaries of women accidentally killed and ovaries removed by abdominal section. Of all these cases he knew the date and character of the last and of former menstruations. In the course of six years Leopold collected forty pairs of ovaries from which to select, and of these he took only those ovaries in which he was wholly sure of the facts. He then found himself with twenty-nine pairs, forming a pretty complete series from the first day of menstruation to the thirty-fifth day after it. In these ovaries he found freshly ruptured follicles at five, eight, twelve, fifteen, eighteen, and twenty-one days after the beginning of menstruation, and in the case thirty-five days after the last menstruation he found a freshly ruptured follicle and a fresh corpus luteum ten to twelve days old. By freshly ruptured follicles he means follicles ruptured within a few hours or a day or two. At all times ripe, prominent follicles were to be found projecting from the surface of the ovary, with thin walls, and surrounded by a circle of vessels. But the largest follicle does not of necessity rupture first. Leopold compares the ripening follicles to a heap of soap bubbles, the smaller of which may burst before the larger. It depends largely on the surrounding pressure; for example, a small follicle may be pushed to the surface and ruptured by the growth of a larger one underneath it.

A very important factor in the rupture of follicles at intermenstrual epochs must be found in coition, which causes a temporary congestion which would be very apt to burst any follicle which might happen to be nearly ripe at the time. Coste found that in rabbits coition hastened the rupture of the follicles, and Wiltshire states that in birds propinquity of the male hastens ovulation. In a word, the observations of Leopold show most decisively that ovulation and menstruation are not by any means always contemporaneous, although a congestion of the ovaries is apt to cause the rupture of any ripe follicles which may be in them, and consequently probably more follicles are ruptured at menstrual times than at others under the influence of the congestion. From this likelihood of rupture at any time he infers that conception in the human female is possible and more or less likely at any time from puberty until the cessation of ovulation.

But the ovulation theory had, and still has, a great influence, in that it explained the cause and process of menstruation most satisfactorily. Pflüger worked it out as follows: the growth of the Graafian follicles caused an irritation of the ovarian nerve terminations, this irritation accumulated in the centres until a certain amount was reached, when a reflex discharge of force took place and the pelvis was engorged with blood, which access of blood to the ovary was enough to cause the rupture of the follicle and the escape of an ovum. The occasional persistence of menstruation after double ovariotomy was hardly needed to disprove this theory; there were instances enough of ovulation without menstruation and of menstruation without ovulation. As to the former of these: ripened follicles and scars from burst follicles are found on the ovaries of infants (Beigel and Sinety). Freshly ruptured follicles are sometimes found in childhood, in the ovaries of women with amenorrhœa, and in the ovaries of pregnant women (Ritchie often found them at four and five months and even at nine months, and these women had not menstruated during pregnancy). In women after the menopause freshly ruptured follicles are often found (Tait). Conception before menstruation comes on is not very rare; in five hundred and fifty cases given by Beigel eight had conceived before ever menstruating. Instances of conception fifteen to twenty-five days after coitus are numerous. As to menstruation without ovulation, we are dependent for the proof of this upon the absence of freshly ruptured follicles in the ovaries of women who have died during menstruation. In Leopold's cases, already alluded to, the cases of five, seven, nine, eleven, twelve, fifteen, sixteen, and twenty days after the beginning of the last menstruation contained no corpus luteum fresh enough to have been formed at the last menstruation. Ashwell relates the case of a woman who had menstruated regularly for years, in whose ovaries was found no rent, scar, or tear. Stedman reported a case where a woman had menstruated regularly nearly to the time of her death, but whose ovaries were found cystic and atrophied.

In regard, then, to this ovarian source of the menstrual impulse, one case of the persistence of menstruation after a double ovariotomy (and there is an abundance of such cases) is of more weight than a dozen cases where menstruation stopped. There is certainly very strong evidence against the ovaries as the source of the menstrual impulse. But there are other sources to be considered, as Dr. Campbell pointed out to the Gynæcological Society recently. Fear, horror, and violent emotions in general are well known to have an immediate effect upon menstruation in many cases. The influence of the mammæ is marked; Dr. Campbell cites two cases of premature menstruation in children caused by mammary inflammation, and a case where long delayed menses returned in a childless woman who allowed her sister's infant to nurse her breasts for a few days in order to quiet it. A change of climate often stops menstruation temporarily; a sea voyage generally delays or hastens the next period, according to the length of time since the last menstruation, and anæmia as a cause of amenorrhœa is so common as scarcely to deserve mention. The relation of menstruation to mental disturbance is closer than is sometimes supposed. Among Schroeder's conclusions, based on 212 female insane, about half of whom were married, he says: "In a majority of cases with mental disease there was menstrual irregularity of some sort," and "These menstrual difficulties were of as early date and were influenced by the slightest symptoms of mental disease, but did not become prominent until the psychosis was developed." The general system as a source of the menstrual impulse seems to have been too little considered by observers.

But whatever the source of the menstrual impulse, the clinical expression of the process is a uterine bleeding; the cause, manner, and result of that bleeding we come now to consider. The tendency has long been to consider menstruation as an excessive pelvic hyperæmia, during which hæmorrhage was caused by a bursting of the walls of the vessels, or, as Pouchet held, by

a desquamation of the uterine mucous membrane. Kundrat and Williams later insisted upon the desquamation, and Williams announced: "Menstruation, then, is neither a congestion nor a species of erection, but a molecular disintegration of the mucous membrane of the uterus followed by hæmorrhage." His observations in 1875 were based on twelve uteri, nine of whose owners had died of acute diseases. He advanced the view that menstruation was only one step in the cycle of uterine changes, which step we happen to see. The uterine mucous membrane, he says, is continually undergoing changes, consisting of rapid growth, insufficient nutrition of the surface layers, and consequent fatty degeneration and denudation, rupture of the vessels consequently, and hæmorrhage. The whole mucous membrane down to the muscular layer undergoes fatty degeneration, and is cast off cell by cell, and consequently the ends of the blood-vessels are laid bare and they bleed. This removal lasts from three to eight days, when from the cells of the *muscular* layer a new mucous membrane begins to form at the internal os and spreads over the whole uterus, covering it in about one week. Of course, when the bleeding has begun it is too late for the fructification of an ovum at that menstruation, and the ovum of the next menstruation, according to Williams and Kundrat, is the only one that can be fructified. Engelmann does not agree to this, but believes that in the neighborhood of a menstruation the ovum fructified is the one belonging to that menstruation. When we reflect that a casting off of the mucous membrane of the uterus, preceded by an albuminoid granulation of its cells, is one of the earlier post-mortem changes, we are the less inclined to accept Williams' results, especially after comparing them with later and more careful observations. Engelmann modified Williams' results by finding the fatty degeneration superficial only, but he found the hæmorrhage due to a fatty degeneration of the walls of the blood-vessels. "In not one of the many uteri examined at such periods was the mucous membrane, or even its superficial layer, found wanting," writes Engelmann.

If we could accept the results of Williams we might most satisfactorily consider menstruation as a disappointed pregnancy, a pregnancy in miniature. When conception takes place a process of nine months or more of uterine increase is gone through, followed by fatty degeneration and desquamation in the puerperal state. When no conception, the process is completed in a little over a week. But, unhappily, Williams' results are untrustworthy, and Engelmann's views are by no means extreme enough to warrant such a theory. But new methods were to come in and new results to be obtained. Moricke conceived the very original idea of scraping with a curette the uterine mucous membrane of his menstruating patients, and in this way obtained an admirable series of fresh pieces of the mucous membrane at all stages of the process. He concluded that the bleeding was due to diapedesis, and that there was no destruction of the mucous membrane, partial or complete, and no fatty degeneration. He points out the ease of falling into error as to denudation of the mucous membrane, and tells of two cases where shortly after death the mucous membrane had disappeared from the body of the uterus in consequence of post-mortem changes.

Lastly, we come to the observations of Wyder, which were recently undertaken to determine whether or no there is denudation of the mucous membrane during menstruation. In eight cases at or near menstruation he found the uterine mucous membrane completely preserved in three, partly missing in three, and completely wanting in two. In one of the cases of denudation given above it is clear that the denudation was not post mortem, in that ciliated epithelial cells were found in the inner layers of a blood clot contained in the uterus; with them were interglandular cells, but no glandular elements. From his observations Wyder gives the process as follows: there is a hyperæmia of the surface vessels, the blood escapes from the vessels by rhexis and diapedesis, presses apart the tissues, and flows in the direction of least resistance, which is to the epithelial surface. There it raises up the epithelium in blood blisters in part, and in part forms erosions by the falling off of epithelial shreds, and the blood flows away. Frankenhauser observed these blisters, which broke and left erosions, not only in the uterus, but also in the vagina of menstruating women. In the latter respect his observations are probably unique. But to return to this raised epithelium; it is disintegrated and carried off in parts, but other parts are not carried away, and although in union with good tissue, are insufficiently nourished and fatty degenerate, which is thus reduced to a very insignificant process. Where there is little bleeding the total damage may be very slight, and restitution follow almost immediately, but where the mucosa shares to any extent it is a longer process. There is great cellular hyperplasia in the middle and lower layers of the mucous membrane. In a word, there is a varying amount of denudation in consequence of the presence of blood in the tissues, which blood is from hyperæmic vessels by rhexis and diapedesis. In the bloody mucus coming from the cervix during menstruation Wyder found in the earlier days ciliated cylindrical cells, interglandular cells, free nuclei, and fat drops, but later in the process nothing but detritus.

But all this gives us no clue to the meaning and cause of menstruation; we are even more badly off than we were ten years ago, for while we had the ovulation theory to fall back upon we could account for menstruation readily enough, and so long as we could hold to the theory of fatty degeneration and denudation we had in menstruation simply a miniature pregnancy, in which the Hindoos agree with us, insomuch that menstruation before marriage disgraces a girl's whole family, being accounted infanticide; but we are less fortunate than the Hindoos in this respect; we can no longer account for menstruation so easily. In the lower animals the heat is most certainly the time of sexual desire, and, so far as the observations on the subject go, the season of ovulation. In the lowest animals in which we find hyperæmia and pigmentation of the genital tract at the breeding season (the foreshadowing of the heat) it can only exist in relation to sexual desire and ovulation, for they have no uterus, and they nourish no young, that is, the reproductive side of the process is undeveloped. The mammalia inherit this seasonal genital hyperæmia; with them also it is the season of sexual desire, but at the same time by it the uterus is put into the best condition for nourishing a fructified ovum, that is the reproductive side of the process.

In woman, on the other hand, the menstrual period is the season of absent sexual desire, and is by no means contemporaneous with ovulation. The human intelligence has rendered woman sexually independent

of the heat; sexual congress is permitted at any time, and, therefore, she is subject to a condition not prevalent in the brute females, she is liable to conceive at any time. It seems as if, in view of the possibility of a pregnancy at any time, and the immediate demands upon her nutritive force which would come from such an event, woman had to be run at a higher pressure than was necessary for the needs of the non-pregnant female. Moreover, she is more different from the man than the brute females are from their males, and the reproductive processes are intensified in her. Since she is run at such high pressure frequent overflows of nutritive material are necessary in the non-pregnant female, and these overflows take place at certain periods of genital hyperæmia, inherited from the lower animals, that is, at the menses. That is to say, the reproductive side of menstruation is emphasized in woman, the sexual side in the brutes.

Any explanation of menstruation in our present state of knowledge must be incomplete and unsatisfactory, but in the meanwhile it may be to some of us a satisfaction to feel that we have at least a remote inheritance in menstruation if we are not able to assign any better cause for its existence.

REPORT ON PROGRESS IN THORACIC DISEASE.

BY FREDERICK C. SHATTUCK, M. D.

Naether [1] contributes an interesting paper on cerebral abscess as a complication of chronic lung disease, reporting eight cases which were under his observation at the Leipzig Clinic during a period of eleven years.

The cases are classed as follows: —

Three of bronchiectasis with retained secretion and circumscribed pneumonia, in one of which there was thrombosis of a branch of the pulmonary artery.

One of chronic purulent bronchitis, the result of patency of the ductus Botalli.

One of fetid bronchitis and ulcerative tuberculosis of the lungs.

Two of gangrene of the lung, in one of which there was also bronchiectasis.

One of old empyema with fistulous opening through a contracted lung.

Seven of the cases were fatal, and in only one of these was the brain abscess single, a fact which shows that the trephine holds out small prospect of relief, and also that additions to our knowledge of the localization of brain disease are seldom to be derived from this class of cases.

In one case of bronchiectasis with sudden right hemiplegia and loss of consciousness, followed by slight aphasia, the patient had so far recovered after about three weeks in hospital, as to request his discharge. He was seen six months later, and had not wholly regained strength in the paralyzed leg. In default of an autopsy the diagnosis of abscess cannot be regarded as absolutely certain, but the age of the patient — twenty-seven — renders apoplexy improbable, and there was no evidence of syphilis or endocarditis.

A case of empyema followed by single abscess in the brain is also reported by Hall.[2] The chest had been tapped and a drainage tube inserted; but the cavity never closed completely, and nearly two years later headache, vomiting, left-sided convulsions, and coma came on. The wall of the cerebral abscess was nearly an eighth of an inch thick, and hard, which shows that the collection of pus was not of very recent formation. In the discussion which followed the reading of the paper before the Clinical Society of London, a member said he had seen two cases within a year in which cerebral abscess followed empyema treated by removal of rib.

Virchow first called attention to a connection between gangrene of the lung and brain abscess, and soon after Biermer published four cases of bronchiectasis with the same complication, which we now know may have its origin in any chronic ulcerating process of the lung or pleura. The metastatic nature of these abscesses seems to be generally admitted, but it is not clear why the brain is apparently the favorite lodgment for the minute emboli taken up by the pulmonary veins. Perhaps the brain is not the favorite seat of lodgment, emboli finding their way in those cases quite as often to other organs; however this may be, it is certainly in the brain that suppuration is set up by preference. Not being able to give a definite answer to this question the author wisely abstains from bringing forward any hypothesis.

It should be added that a microscopic examination of the pus afforded only negative results. Weigert found in it various low organisms, but they were peculiar neither in shape nor in their behavior toward staining fluids.

ENCAPSULATED EMPYEMA SIMULATING PERICARDIAL EFFUSION.[3]

A man of thirty-two was admitted into hospital with the history of acute disease of four weeks' standing, his health having previously been good. The physical signs pointed clearly to fluid, probably purulent in character, in the left pleura; the chest was tapped, pus was drawn off, and the next day an incision made in the back, but satisfactory improvement in the symptoms did not follow, although the drainage was good. Some days later a careful examination was made and it was noted that the cardiac region was still prominent and tender on pressure; the heart's impulse could not be seen or felt, though there was a slight undulation in the fourth interspace just inside of the mammillary line. The area of dullness had the triangular shape characteristic of pericardial effusion, and the heart's sounds were distant and feeble, though clear. An exploring needle was introduced in the third interspace, the seat of greatest prominence, and pus was withdrawn. The same afternoon an incision was made at the seat of puncture, and pus, estimated at one and a half to two litres in amount, was evacuated, the discharge at first coming in jets synchronously with the action of the heart. The finger introduced into the wound felt the heart pulsating. The patient was more comfortable for a time, but died three days later with symptoms of peritonitis and pyæmia.

The pericardial cavity was obliterated, the membrane being nearly as thick as the finger, and it was found that the abscesses opened by the knife were both pleural and without intercommunication. The anterior collection of pus at its inner side lay in contact with the pericardium, and thus simulated closely effusion into that cavity. It is difficult to see how the mis-

take in diagnosis, which worked in no way to the disadvantage of the patient in this case, could have been avoided. Such cases must be very rare, but it is well to know that they occur: the author suggests that possibly among the cases of incision of the pericardium with recovery and consequent lack of post-mortem evidence, there may have been one similar to his — external, not internal, pericarditis.

A PRACTICAL POINT IN THE TREATMENT OF PLEURAL EFFUSIONS.

Dr. Broadbent,[1] in a clinical lecture, says that when he hears distinct bronchial breathing generally over the chest in cases of pleural effusion, he feels sure that a consolidated lung is immersed in the fluid, and he consequently does not tap unless the symptoms are so urgent as to demand interference. A solidified lung cannot, of course, expand, as does one which is simply collapsed or even compressed, unless it is bound down by adhesions; and experience has shown him that on the resolution of the pneumonia the fluid is usually rapidly absorbed.

He seems to hold the sound views that with grave symptoms a pleural effusion should be withdrawn, whatever the complication; that the course of moderate effusion may often be shortened by tapping; but that, if the lung be consolidated, — one evidence of which is the persistence of bronchial respiration over the whole or a large part of the chest, — it is better to wait, if the condition of the patient warrants such a course.

THE MECHANISM OF THE FRICTION SOUND OF PLEURISY.

Moxon,[2] in common with many others, is satisfied that he has often heard pleural friction, so called, over portions of the chest occupied by fluid, where, consequently, the layers of the membrane, not being in apposition, could not rub. Is the sound, therefore, not produced by creaking of the lymph on the pleura when it is stretched in inspiration?

CHEYNE-STOKES RESPIRATION IN AN INFANT.

Dr. O'Connell, of Sioux City, reports the case in the *British Medical Journal*.[3] He delivered a patient, after an easy labor, of an apparently healthy child, three weeks before full term, according to the patient's reckoning. Normal respiration was speedily established. Five hours after birth the child became ill, and he arrived an hour later to find it apparently dead and laid aside. "On my moving the body the child took a spasmodic inspiration, like a first breath. After a few seconds another inspiration followed, then a third, and so on, with gradually decreasing intervals, until respiration became normal. The heart's action, too, became normal, and the body grew warm and natural in color. After a short time his breathing began to grow quick, and ran up to hyperpnœa, and then declined to apnœa. During the apnœal stage, which lasted five minutes, I failed to perceive the least motion of the thoracic or abdominal walls, neither could I hear the child breathe. With the stethoscope I could hear the heart faintly beating forty times per minute. No drug of any kind had been given to the child. Nothing amiss could be found on careful examination of the body. The bowels had moved spontaneously. Still, as it would twist, draw up the lower limbs, and cry, as if from colic, an enema of simple tepid water was administered, which caused a large alvine evacuation, with seeming relief. At the times when the child appeared to suffer from the recurrent abdominal pain I noticed slight twitching of the facial muscles, with rolling of the eyes. Then followed a paroxysm of Cheyne-Stokes respiration. In seven hours there were a dozen attacks of this abnormal form of breathing. The child died in an apnœal stage twelve hours after birth. No necropsy was allowed.

"Both parents drank a good deal. During her pregnancy the mother partook freely of beer, if not of stronger drinks. She was also suspected, on good grounds, of using bromides, chloral hydrate, and opiates. Her first child, a male also, was very puny and delicate. It was a typical example of Cheyne-Stokes respiration. It is very unusual to see the apnœal stage last so long as five minutes, but I took the time by my watch. I am unable to suggest any explanation in this case."

HEART DISEASE IN BERLIN AND MUNICH.

A discussion has been going on of late as to why heart disease is more than twice as common in Munich as in Berlin, a fact shown by the statistics of the autopsy rooms of the hospitals in the two cities, the material coming, of course, in both from the same class of the community. Schmidbauer proved the fact of the predominance of heart disease in Munich, and then explained it by the enormous amount of beer consumed in that city, 566 litres annually for each inhabitant. His conclusions excited considerable comment, and among his critics is Beetz,[4] who shows that, perhaps from climatic causes, articular rheumatism is more common in Munich in almost exactly the same proportion as heart disease, a fact which goes far to invalidate Schmidbauer's theory. Hypertrophy of the heart is not a direct result of the abuse of alcohol, and, according to Schrötter, an increase in the amount of the blood resulting from the ingestion of large quantities of fluid does not increase the size of the left ventricle, as, on theoretical grounds, it might be expected to do. The consumption of such an amount of beer as is customary in Munich involves the passing of a vast deal of time in close rooms, without bodily exercise, and this must materially enhance the deleterious influence of the beer itself on the general health and the nutrition of the cardiac muscle. The discussion affords a fresh illustration of the great care which should be exercised in drawing conclusions from statistics, and is not without interest to us in America, where the consumption of beer is so steadily on the increase.

CARDIAC MURMURS AUDIBLE AT A DISTANCE FROM THE BODY.

Out of about 900 cases of heart murmur studied by Lublinski[5] during the last six years in three the adventitious sound could be heard by the naked ear at distances of ten to seventy-five centimetres from the chest wall. Two were cases of aortic disease, one of stenosis of the pulmonary orifice. In every case the patient was conscious of the abnormal sound, which interfered with the sleep of one, and caused great anxiety to a second, as well as to his friends, who could also appreciate it.

1 Lancet, 1884, i., pp. 925 and 971.
2 Lancet, 1884, i., p. 53.
3 1884, i., p. 220.
4 Deutsch. Med. Wochenschrift, 1883, p. 720.
5 Zeitschrift f. klin. Med., 1884, p. 523.

Murmurs of this great intensity are most common in aortic stenosis, which, when pure, causes great hypertrophy of the left ventricle without much dilatation of the cavity; they have, however, been observed in all valvular lesions save those of the tricuspid and in pulmonic regurgitation. In some cases the great intensity is lost when the heart fails for any cause, which shows that the vigorous contraction of a powerful heart muscle may be a necessary factor in their production; but in other cases they are persistent, largely irrespective of the force of the heart's action. The three cases referred to, for instance, entered the hospital for cardiac failure in different degrees, were much benefited by treatment, but the change in the murmurs was very slight. In such cases Lublinski thinks it probable that the valves are either very rigid from cretified deposits, or markedly fenestrated, or else that there has been rupture of one of the chordæ tendineæ. Occasionally aneurismal murmurs can be heard at a distance; and Stokes reports two cases, in young women, where the intense murmur was probably functional, as it, together with the symptoms, disappeared under treatment.

DISEASE AT THE TRICUSPID ORIFICE.

It would seem that not only is disease much more common in the right side of the heart than has been supposed, but that it is, in adults at all events, generally acquired, and not congenital, as has been stated by nearly all the recognized authorities. New light has been thrown upon this subject by Fenwick [1] and Duroziez,[2] especially the former, who has collected seventy cases of tricuspid stenosis, and fifteen of incompetency.

Tricuspid is always associated with mitral stenosis, and, in more than twenty-five per cent. of the cases, with aortic stenosis also. Duroziez, — who contributes fourteen of the cases, — it is true, alludes to one in which the constriction was uncomplicated, a case not included in Fenwick's collection. He examined the patient during life, and heard only a systolic murmur over the lower portion of the sternum, but he did not see the heart himself, the autopsy having been made by an interne, who reported that the tricuspid admitted one finger with difficulty, and that the other orifices were healthy. In fifty per cent. of the cases there was a clear history of acute or subacute rheumatism, a proportion which holds good for valvular disease to which no suspicion of congenital origin attaches. Nearly all the cases were in patients more than twenty years of age, and one in a woman of sixty-four; most of them were between twenty and forty. The subjects of the disease were females in all but eight of the seventy cases, a fact which, to say the least, renders it highly improbable that the origin is congenital. Duroziez states that pure mitral stenosis is also nearly confined to the female sex. Fenwick thinks such an assertion too strong, but promises to investigate the point thoroughly. He explains this peculiarity of sex as follows: "I contend that it results, in the vast majority of cases, not, as is still commonly taught, from congenital malformation, or even from intra-uterine disease, but from disease in adult life, and simply and solely from an agglutination of the granulating edges of two opposed and inflamed valves, and this, too, for a purely mechanical reason. I would illustrate my meaning by an example. Let us consider what takes place in any ordinary deep granulating wound on the surface of the body. If the edges be kept in apposition under favorable circumstances direct union will occur between them. If only a limited amount of cohesion be obtained the parts will unite from the bottom, but if they be kept constantly and widely apart each side will separately scab over, heal, and contract. And as on the skin, so, I take it, is it with the valves. If they have a certain amount of rest nature will do with them as she does under like conditions anywhere else. The apposed lines of granulating edges will unite, and stenosis be produced. If the parts are in constant and considerable separation each inflamed border will dry up and cicatrize, and direct incompetence will, of course, ensue. And I contend, therefore, that stenosis is more common in women, because in them the life work is less onerous, the heart action less powerful, the back pressure, therefore, slighter, and consequently the valve disturbance less than in men. And then in men the muscle-straining labor, the compensating heart power more violent, and so the comparatively greater *vis a tergo* and valvular action, keep the inflamed edges non-adherent till nature has puckered and shrunk them, and so produced primary incompetency. Common sense, therefore, furnishes a simple mechanical explanation of the facts which I have shown with relation to the sexes. If further proof be needed it is readily obtainable." To understand fully what follows it must be prefaced that of the fifteen cases of primary tricuspid insufficiency eight were in men and seven in women, a very different proportion from that which obtains in women, though it could be wished that the number of observations were greater. To quote again, "In every case of tricuspid stenosis in men I showed that acute rheumatism had been suffered from, and so severely or so often as to have disabled the patient, and so have changed for a time the hard-working man into a bedridden invalid, and for that period, of course, have placed the heart action at or below that of any woman. On the other hand, in the female cases with incompetency the occupations of only two are noted, but these were both intemperate, and both hard workers, with heavy weights to lift or carry, — one as a fruit seller, the other as a washerwoman, and so their work, and, presumably, their cardiac strain, was probably as hard as that of most men."

It would thus seem that tricuspid disease has been thought extraordinarily rare, chiefly because it has not been looked for carefully, and Fenwick makes an appeal to the members of the Pathological Society in future heart cases to take particular note of the circumference of the tricuspid orifice and the condition of the valves. According to Bizot the average circumference is normally one fifth of an inch less in women than in men, while in the mitral the difference in the sexes is only one one hundredth of an inch.

Duroziez confesses that in only one case in which he made the diagnosis during life has he had the opportunity of verifying it after death. The murmur occurs at the same time, of course, as that due to the mitral constriction, and the latter obscures the former, or, the valves lying very near one another, the murmurs are merged together. Distention of the jugular veins is common alike to constriction and insufficiency at the tricuspid, and it is well known that the latter condition of the orifice often occurs in cardiac failure secondary to mitral disease, simply from over-distention

[1] Trans. London Path. Soc., 1881, p. 42; 1882, p. 64; 1883, p. 35.
[2] L'Union Médicale, 1883, December 23 and 25.

of the right ventricle. If the jugulars are so distended that their valves become incompetent the blood wave can be propagated from the right auricle into those vessels, and, theoretically, presystolic pulsation should be seen in them. Such pulsation does not seem as yet, however, to have been observed.

Recent Literature.

Elementary Principles of Electro-Therapeutics, for the use of Physicians and Students. Prepared by C. M. HAYNES, M. D. Chicago, Ill.: The McIntosh Galvanic and Faradic Battery Co.

This is apparently written for the purpose of increasing the sale of the company's batteries. The batteries of no other maker are described; McIntosh is appended to all the apparatus. We do not believe in any such partisan medical literature. As well might a book on surgery be "prepared," one quarter of which should be devoted to descriptions of the instruments manufactured by the firm printing the work. The McIntosh Company did not need such an advertisement.

The directions for use of electricity in all the various affections to which it can be applied are very full. In many respects the therapeutics of electricity is given very satisfactorily; there are, however, several careless statements, and some omissions. While the book is a safe guide to the use of the various forms of electricity, it cannot be recommended as a scientific production.

The National Dispensatory: Containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicines; including those recognized in the Pharmacopœias of the United States, Great Britain, and Germany, with numerous References to the French Codex. By ALFRED STILLÉ, M. D., LL. D., and JOHN M. MAISCH, Phar. D. Third Edition, thoroughly revised. Philadelphia: Henry C. Lea's Son & Co. 1884.

This work, as indicated by its title page, may be regarded as a general commentary upon the last edition of the Pharmacopœias of the four chief civilized nations, although the Pharmacopœias of the United States and of Germany, both of which appeared in the year 1882, and are greatly in advance of those of all other nations, form the chief basis of this revision. The new French Codex, however, which was only published this year, is yet incorporated. The references to the British Pharmacopœia, the last edition of which appeared in 1867, although some later additions were made in the reprint of 1874, remain unchanged in this revision of the Dispensatory.

In addition to the strictly official articles, a large number of extra-pharmacopœial drugs and preparations have been added to those in the previous editions. It is now illustrated by three hundred and eleven wood cuts, many of them representing microscopic structure.

The most recent reviews of the physiological action, so far as it relates to therapeutics, are given. The doses are given both in the metric and the older apothecaries' weights. In this connection it is interesting to note that the old dose for laudanum remains unchanged, and thus this work does not support the statements so widely disseminated by those interested to break down our standard for drugs under the adulteration law of this State.

The work is one of which all physicians and pharmacists would find it greatly to their advantage to have a copy.

B. F. D.

FOREIGN BODIES IN THE EYE.

DR. AGNEW, of New York, writes:[1] "When a patient comes to you complaining of a sensation as if a foreign body were in the eye, you should first examine the eyeball from every point of view. You should then turn over the eyelids and examine their inner surfaces. And here I am reminded of a source of error to which I would call your attention. A few days ago a case came under my observation which illustrates the point. The gentleman had had occasional attacks of conjunctivitis for a year or more. He had then a sensation as if a foreign body were in the eye. On turning out the right lower eyelid, all that was revealed to sight was a slight redness of the conjunctiva. But there was something in the way in which the sensation of a foreign body in the eye was exaggerated that made me suspect he had a single inverted eyelash. Ordinarily he felt as if some irritant was there which was tolerable, but suddenly there would be a cramp-like action of the eyelid, the irritation would grow rapidly worse, and the eye would fill with tears, followed by the discharge of a little mucus, and temporary relief. His beard was of a sandy color, his hair was light brown, and his eyelashes were almost colorless. I looked very carefully along the edges of the lids in search of inverted eyelashes, and saw, on the innermost edge of the lower lid, a slight curving of the inner angle. By allowing a tear to gather upon this inner edge, I saw that there was a difference in refraction in different portions of the tear, and it soon became evident that a delicate decolorized eyelash was there, which, instead of growing from the outer edge of the lid, sprang from the free edge of its inner border. I turned the lid over, and found that this delicate eyelash, which was between the edge of the lid and the eyeball, had been so long caught in that position that it had worn a little groove in the edge of the eyelid; the spasmodic action of the orbicularis, from time to time, so long continued, had embedded the eyelash in the substance of the lid. I removed it, and no further trouble was experienced. This patient had been treated in Europe for acute conjunctivitis several times, and it is possible that the eyelash was on those occasions the cause of all the trouble. An operation will be required to destroy the follicle which produced the misplaced eyelash. So, when a patient comes to you complaining of a sensation as though there were a foreign body in the eye, between the eyelids and the eyeball, you must first look for conjunctivitis. Whether this be present or not, you should then proceed to examine the eye very carefully to see whether a foreign body be present or not. Scan carefully the whole surface of the cornea and of the scleral conjunctiva, and then turn over the upper eyelid and carefully inspect its inner surface. You may then scrutinize the edges of the lids, as I have described, in order to see whether the source of the irritation be an inverted eyelash."

Medical and Surgical Journal.

THURSDAY, AUGUST 28, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

TWENTIETH ANNUAL REPORT OF THE BOSTON CITY HOSPITAL.

THE present report of the Trustees and Superintendent of the Boston City Hospital for the year 1883–1884 is the twentieth, and covers the completion of the first score of years since the foundation of the hospital. The report therefore presents, in addition to the usual details of a year's work, a summary of results for each year of the twenty, by which a general idea of the hospital's growth in size and efficiency may be obtained.

The whole number of patients in the hospital during the past year was 5061, and they were under treatment an average of 20.7 days each at an average cost to the city of board for each patient of $8.70 per week. The largest number of patients in the hospital at any time was 348; the smallest number in the hospital at any time was 235; the daily average number of patients was 286.29. The number of patients treated in the out-patient department, classified according to their diseases, was as follows: Medical diseases, 3156; surgical diseases, 6493; diseases of the eye, 1632; diseases of the ear, 382; diseases of the skin, 1023; diseases of women, 465; diseases of nervous system, 475; diseases of the throat, 615; total, 14,241.

During the past year the largest number of patients in the hospital at any one time was 348, seven more than the previous year; the smallest number at any one time was the same as last year, 235. The average length of stay was one and one half days less. The number of weeks' board was seventy-five more. Last year 5991 applicants were examined for admission; this year, 6152. Last year 1568 applicants were denied admission; this year, 1372, or 196 less. This has been accomplished only by a more rapid movement in the population of the hospital, the cases being more largely of an acute nature sooner recovered; and also by a compulsory movement of incurable cases to the charge of their friends or to some other institution.

The number of patients admitted with accidental injuries was 531. Of all patients admitted 173 died within forty-eight hours after admission, which is twenty-four more than last year. The rate of mortality was .094 per cent. If from the total number of deaths we deduct those brought to the hospital in a dying condition, the annual mortality is reduced from .094 to .059.

The net cost of maintaining the hospital was $2447 less than last year. The cost of subsistence was less, but salaries and wages in many instances have been increased, the trustees deeming it a wise economy to secure and retain trained and tried officers, nurses, and employees, whose services unquestionably increase in value with increased experience.

Since last year the city has made an appropriation of $40,000 to build a much needed home for nurses. This building, now under way, will be four stories high, built of brick, and designed to accommodate fifty-nine nurses, most of the rooms being intended for one occupant. The rooms now occupied by nurses will thus become available for patients, and the capacity of the hospital, now unequal to the demands made upon it, enlarged from 380 to 450 beds. The home for nurses is thus the first of the pressing needs insisted upon in previous reports to meet with practical recognition. Better accommodation for the out-patient departments, increased facilities for the care and isolation of contagious diseases are crying necessities, and would repay the city many fold for the comparatively small outlay demanded. The superintendent, Dr. Rowe, justly says: "Scarlet fever and diphtheria have been epidemic for several years in this city. This will, undoubtedly, continue until there are sufficient and suitable hospital wards to isolate every case, so that the last residence of the patient can be fumigated and rendered non-infectious by the destruction of the disease germs. The same policy should be pursued with diphtheria and scarlet fever as is now in force with small-pox. When this is done there may be hopes of eliminating these devastating diseases, and the mortality, especially among children, greatly diminished."

These are not the kind of things, however, in which the ordinary city politician is interested. A rate of taxation of $17.50 a thousand is not, in his estimation, too much for the patient tax-payer, but the justification is found elsewhere than in rescuing his humbler and poorer fellow-citizens from disease and death.

The controversy between the trustees and the State, as represented by the Board of Charity, over the cost of treating the large number of cases having no legal settlement, still continues, and involves an annual sum of about $27,000 over and above the amount accepted by the State, which is now added to the expenses of the City Hospital.

DIME MUSEUMS AND VENOMOUS SERPENTS.

THE account of the death of a showman, named Reilly, in New York last month, some twenty-seven hours after having been bitten by a large trained diamond rattlesnake, five feet in length, from Mexico, is not destitute of interest in view of the recent multiplication of dime museums and small shows of which such reptiles, with the attendant snake charmer, so often form a part. Moreover, although the rattlesnake, in common with other venomous reptiles, has become extremely uncommon in the neighborhood of our large cities and throughout our Eastern States (even the Blue

Hills of Milton having almost lost their distinction as its *habitat*), they are extremely common and troublesome in the Southern and Western States and Territories, as, for instance, Texas and Nebrasaka, where stimulation is resorted to both as prophylaxis and treatment, sometimes judiciously, and too often heroically. In the case of Reilly it was reported that as soon as bitten he applied his lips to the wound and exerted all the suction of which he was capable, and then partook very freely of whiskey, a quart being stated as the amount. At the hospital to which he was taken the treatment was mainly a free administration of whiskey and ammonia subcutaneously and hot poultices locally, — a treatment shown by the result, as might have been anticipated, to be quite unavailing.

As some of the most valuable recent contributions toward an elucidation of the composition and action of the venom of this particular serpent have resulted from the investigations of our own countrymen, — we allude especially to Drs. S. Weir Mitchell and Reichert, of Philadelphia, — it would seem that, rare as they may be, we should be prepared to treat such cases of poisoning intelligently when they occur, and our snake performers should, in imitation of their more practiced *confrères* in India, prevent their occurrence by a previous careful removal of the old and supplementary poison fangs of the reptiles they exhibit. That ignorance or recklessness, and not a scrupulous desire to give patrons an honest measure of horror for their entrance money, is the cause of such neglect, seems, from what is known of dime museum management in other particulars, unquestionable. In this very establishment the partner, one Clark, eat fire, and Mrs. Clark represented the customary Circassian girl; the snake charmer's conscience should therefore have been sufficiently indurated to permit his performing with fangless snakes, and his histrionic talents sufficiently developed to enable him to imitate his eastern prototype again in feigning the necessary symptoms of poisoning, when struck by his pets, applying his secret charms, and gradually recovering.

The mode of ejection, the composition, and the action of the venoms of different classes of serpents, though differing in details, have much in common, and the investigations of Mitchell in this country upon crotalus poison, and of the officials of the Calcutta Snake Poison Commission, Messrs. Wall, Richards, and others upon viperine (Daboia) and cobra poisons, supplement and confirm each other in a marked degree, as far as treatment is concerned, at least. Dr. Joseph Ewart, for several years at the head of the Calcutta Snake Poison Commission above referred to, writes a correspondent, commenting upon Reilly's misfortune: "It is a pity that our being devoid of any antidote was not at once recognized and acted upon. Some years ago I strongly represented this, as others had done, and urged excision as the only hope of saving life; and since then my old assistant, Dr. Wall, has proved by experiment that if done in time by careful dissection, under an anæsthetic, and the resulting wound be freely washed out by a solution of permanganate of potash, the whole of the virus injected into the cellular structures may be promptly removed and otherwise certain death be successfully averted." In connection with incision or excision the question of time is the important one, and to increase the favorable chances a ligature should always, when practicable, be applied between the bitten part and the heart.

Dr. Ewart elsewhere writes:[1] "Although of late years much has been done to illustrate the action of snake poison, to ascertain its pathological effects and its chemical composition, we have not as yet discovered an antidote. We have ascertained that liquor potassæ, permanganate of potash, nitrate of silver, and other reagents which have the power of precipitating its active principles, when mixed with it out of the body render it harmless. M. Lacerda thought that he could neutralize it when deposited in the tissues by following it up with injections of a one per cent. solution of permanganate of potash. If this could be done before a fatal quantity had reached the blood, and all the poison injected could be brought under the influence of the alleged antidote, it might succeed. Wall has shown that it has no antidotal power when put into the blood in large quantities. And the practical impossibility of precisely following the course the poison has taken in the soft structures renders it a very uncertain and doubtful remedy. The antidotal power of intravenous injections of liquor ammoniæ was disproved by Fontana a century ago."

Weir Mitchell reached very similar conclusions in 1861[2] and in 1868.[3] Excision or even amputation, incision with free suction, as by cups, supported by the early ligature, applied continuously or intermittently, are the only means which can be relied upon to avert the issue in dangerous cases, and cases are, in general, severe according to the size and vigor of the rattlesnake, and the entrance of one or both fangs. The severity of the early symptoms may, as a rule, determine the justifiability of a resort to so serious a measure as amputation. Mitchell failed to find any general antidote or any reliable local application, such agents as tannin, iodine, etc., merely checking locally the usual tendency to hæmorrhage from the capillaries. The benefit of suction by the mouth, unless preceded by incision, or unless the wound itself be such as to permit free hæmorrhage, is but slight. The process of suction is safe enough for the performer, unless there should be abrasions of the mucous membrane, for Mitchell has shown that rattlesnake venom is absolutely harmless when swallowed, because it is incapable of passing through mucous surfaces, and because it undergoes some change during digestion.

Both our own and the India authorities agree that reliance must be placed mainly on the early removal of the poison. Stimulants are useful, as in other depressing assaults, to support the strength. With stimulants and the intermittent ligature the system will undoubtedly often support an attack which would other-

[1] Poisonous Snakes and their Poisons, November, 1883.
[2] Treatment of Rattlesnake Bites, etc., etc., North American Medico-Chirurgical Review, March, 1861.
[3] Toxicology of Rattlesnake Venom, New York Medical Journal, January, 1868.

wise prove fatal. The virus of poisonous snakes is not injurious to their own species, nor does it affect injuriously any of the venomous varieties of the Ophidia, and Dr. Ewart still hopes for the discovery, from a study of these points, of a successful and reliable antidote for man.

MEDICAL NOTES.

— A fact of some political significance is announced from France, to wit, that the French government has bestowed the order of the *Legion d' Honneur* on Dr. Koch, in recognition of his services in the cholera district rendered during his short stay in France.

— The *Lancet* remarks, apropos of capital punishment in France: "At length it is beginning to be recognized in France that the brain of a decapitated criminal lives, and consciousness is maintained for an appreciable time, which to the victim may seem an age, after death — an opinion we strongly expressed many years ago. This ghastly *fact* — as we have no doubt it is — being perceived, it is beginning to be felt that executions cannot any longer be carried out by the guillotine. Prussic acid is now proposed. If instantaneous death be desired, this is clearly inadmissable. The period taken to terminate life by poison of any kind must needs vary greatly with the individual. In not a small proportion of instances we fancy death by prussic acid would be considerably protracted, and although long dying is not so horrible as living after death — so to say — yet it is strongly opposed to the interests of humanity to protract the agony of a fellow-creature dying by the hand of justice. Electricity is another agent suggested. We doubt the possibility of applying this agent so as to destroy life instantly. We confess that, looking at the matter all round, we incline to think that hanging, when properly performed, destroys consciousness more rapidly, and prevents its return more effectually than any other mode of death which justice can employ. It is against the bungling way of hanging we protest, not against the method of executing itself. That is, on the whole, the best, we are convinced."

— At the conference recently convened by the Medical Society and the National Health Society of Great Britain, the subject for discussion on the 1st instant was Recreations and Gymnastics. After the reading of several papers Sir James Paget maintained that the English system of gymnastics, — namely, outdoor games, — was far superior to the German, Swedish, or any other system.

— The *Leisure Hour* relates the following anecdote of Abernethy, which illustrates his abhorrence of garrulity on the part of his patients, and how a bright woman, by her cleverness in humoring this well-known trait of his, succeeded in winning the rare meed of a compliment from the great surgeon. She made him three visits, and the conversation at each of them is worthy of attention by busy practitioners and "case-takers" in general. At the first visit, holding out her wounded finger as she entered the surgeon's consulting room, the lady allowed him to open the following conversation: Abernethy — Cut? Lady — Bite. Abernethy — Dog? Lady — Parrot. Abernethy — Go home and poultice it. The second visit was fruitful of three utterances over the extended finger. Abernethy — Better? Lady — Worse. Abernethy — Go home and poultice it again. At the third interview the finger, extended for the third time, occasioned these words: Abernethy — Better? Lady — Well. Abernethy (with enthusiasm, while his twinkling eyes showed his proper appreciation of the lady's fine humor) — 'Pon my honor, madam, you are the most sensible woman I ever met. Good-by!

— The "fresh air" philanthropists are doing their good work at the present time. That their kind intentions are not always met with the appreciation that they deserve seems to be indicated by the following anecdotes which we clip from a non-medical contemporary: —

A woman at Litchfield, Conn., had agreed to take a boy and his sister for their second visit to the place. The boy came alone, however, and being asked about his sister, replied: "Mother would n't let her come to Litchfield this year. She says she got the malaria coming out with the fresh air fellers last year." The children live on Baxter Street, New York.

Again, among the young waifs brought out from the city a young lad stood looking at the circus pictures when a couple of ladies came up, and one of them, pointing to the boy, said: "That is one of the 'fresh air' children." The other lady remarked, "He looks as though he might be; I 'll speak to him." So she said, "My boy, are you one of the 'fresh air' children?" "Well," he replied, "not so very d——d fresh!" Which ended the dialogue.

— A writer in the *Southern Clinic* advocates the following plan of using chloral hydrate as a vesicant: Powdered chloral sprinkled on adhesive plaster and melted by a gentle heat (not more than enough to cause plaster to adhere to the flesh) is applied, while warm, to the part where the blister is wanted; within a few minutes a gentle heat is felt, increasing in intensity for a short time, then gradually easing off, and at the end of about ten minutes the part is free from pain. At the expiration of this time, or as soon as the pain has subsided, the plaster, if removed, will disclose a surface as effectually blistered as by a cantharidal plaster after six hours. Thus within about ten minutes the work of an old-fashioned blister is accomplished, with many advantages over the latter: (1) rapidity of action; (2) the ease of application; (3) the non-occurrence of strangury; and (4) it may never be taken off to have the blister dressed, but may be allowed to remain until the plaster loosens and comes off itself, the blistered surface in the meanwhile healing kindly.

— That the "love of money is the root of all evil" seems to have received confirmation in a novel sense from the observations of Professor Rejnsch at Erlangen (*Allg. Med. Centr. Z.*, 31, 1884), who on examining a number of coins found, to his astonishment, that all coins which showed some encrustation, little

sediments, etc., on their surface, contained living bacteria. Reinsch then collected coins of all nationalities, and made the same observation in all coins that had been in circulation for a number of years. When the adherent dirt particles are removed with a perfectly clean (aseptic) knife, and dissolved in distilled water, a sufficiently powerful microscope will at once reveal the bacteria. The dirt sticking to coin seems to offer to these microzymes a soil specially fertile and favorable to their development. Considering the immense circulation of money passing through millions of hands it may be probable that coins form no small factor in the transfer of zymotic disease. If this be true it would seem probable that a paper currency, from its greater uncleanliness, would serve as a more favorable channel for the transfer of infectious diseases than a metallic one. Zymotic considerations, therefore, may be added to the politico-economic arguments against the Greenback party. Immersion in a boiling solution of caustic potash, which has been found to remove all the bacteria from coins, is hardly practicable in the case of bills. Yet in spite of the danger there will probably be found those who will neglect to repudiate and discard this carrier of infection.

— A recent paper by Assistant-Surgeon R. C. Newton, United States Army, in the *Medical News* (July 5th) gives the particulars of an outbreak of intermittent fever in an army post in Indian Territory, with a topographical sketch of the camp. A creek which carries much floating vegetable débris in the spring freshets, and deposits it along its banks as it recedes, is to the north of the post. The north wind has been observed to be the malaria-bringing wind. The barracks are so disposed that certain ones are directly exposed to this north wind, while others are sheltered by the former buildings. Figures as to the number of cases and the total days' service lost on account of malarial sickness show a marked correspondence to the amount of exposure of the several barracks to this north wind. It is also worthy of note that the troops stationed at this post are colored, and that the disease is as frequent in them as in whites.

— An interesting case, unfortunately attended with a fatal result, is reported by the *Medical Press* (July 16th) from Grays, in Essex, England, the victim being a little girl, three years of age, the daughter of an officer of the Shaftesbury training ship. While on the way to school, accompanied by an elder child, the deceased tripped and fell, and in doing so struck the angle of the right eye with the sharp point of a piece of slate pencil held in one hand. A slight amount of hæmorrhage ensued; but after the shock of the accident the child seemed none the worse for some time. In about three weeks, however, she complained of pain in the eye and head, and symptoms of acute inflammation rapidly supervened; convulsions set in, and in a little more than twenty-four hours the little sufferer was dead. The medical evidence at the inquest attributed the result to meningitis induced as a consequence of the injury to the eye, the wound inflicted on which had, however, entirely healed; and the case possesses many features of interest in this connection. At present no details have been given respecting the constitution of the patient, except that she is described as having been a "very healthy child;" but the occurrence of such cases has been sufficiently often recorded to make it not improbable that a correct explanation has been given in this instance.

— An important legal decision was, according to the *Maryland Medical Journal*, recently rendered in one of the Western States which may have a very important influence in preventing suits for damage from malpractice. Two surgeons had been employed in a case, but in different ways, and for different compensation. The patient not being satisfied with the treatment refused to pay either of the bills rendered. A suit was brought by one of the surgeons and a judgment was given in his favor by the court. The patient then brought suit for malpractice, but the surgeon put in as defense that this question had been adjudicated in the previous suit and could not be again raised. This defense the court held to be a good one, deciding that the former suit was a bar to the second one. According to this decision a surgeon need not fear a suit for damages from malpractice if the value of his services has been acknowledged in a suit to recover the amount of his bill. In other words, the surgeon may possibly forestall a suit for damages from malpractice by instituting a suit for the amount of his professional services.

— The next International Medical Congress will be held in Washington, the invitation of the American Medical Association conveyed through Dr. Billings at Copenhagen having been accepted.

— The annual revenue of the British Medical Association, we learn from its official organ, exceeds $100,000. One half is derived from annual subscriptions of members, and nearly as much is obtained from advertisements and sales of the journal, the remainder being from interest on investments. The excess of income over expenditures in 1883 was $12,020. The Association now has over $85,000 invested in government and railway securities.

NEW YORK.

— The second annual report of the Central Council of the Charity Organization Society, which has just been published, shows that during the last year the agents of the Society made 23,091 reports in regard to applicants for assistance. The Society keeps a street register on cards in such a way as to group together all the families applying for charity or represented in the city penal institutions, and 19,658 houses are included in it. In one section of the city, the report states, there were found three short blocks with eleven liquor shops in each, the bulk of the support of the latter being evidently drawn from the gifts of the benevolent to the wretched denizens of the locality. "This picture," it continues, "serves to suggest the two leading causes of the vast pauperism with which this Society has undertaken to cope — intemperance and misplaced alms." Of 694 persons found begging in the streets fifty-five per cent. were

able-bodied; forty-one per cent. could have earned their support wholly or in part; and but four per cent. had apparent excuse for asking aid of any one. The following are samples of some of the cases investigated: A white-haired man was "blind" on Broadway by day, and at night a well-known poker player in Baxter Street, with full powers of vision. A paralyzed tramp was in partnership with an able-bodied one. The latter would stay at home and write heart-rending appeals, which the former carried around, and at night they would divide the profits. Eighty-nine of the 694 street beggars were committed to Blackwell's Island for various terms.

— The annual meeting of the American Society of Microscopists was held at Rochester, August 19th, 20th, and 21st. During the proceedings an address was delivered by Rev. Dr. W. H. Dallinger, president of the Royal Microscopical Society, and Prof. Alfred N. Bennett, of London, who also came as a delegate from the latter Society, read a paper on Fungi Found in Sewage Effluvia. Among the other papers was one on The Hair Microscopically and Medico-Legally Considered, by Dr. William J. Lewis, of Hartford. The sessions were concluded by an evening reception in the State Arsenal, tendered by the Rochester Academy of Science.

— Prof. Frederick S. Dennis, of Bellevue Hospital Medical College, has filed plans for the Carnegie Laboratory, for the construction of which Mr. Andrew Carnegie has presented the college with $50,000. It is to be built on Twenty-Sixth Street, opposite the hospital grounds, and will be fifty feet square, and seventy feet in height.

Miscellany.

SCIENCE IN TRADE.

The *Sanitary Engineer*, speaking of the application of the scientific spirit to the things of common life, says: —

"The importance of scientific investigation in sanitary matters is a thing we have often had occasion to insist on, and is, in fact, the urgent need of the present day. This is well known and generally assented to by the public, and the fact that a general demand for it exists is sufficiently proved by the vast amount of pseudo-scientific literature which is being produced as the best means of advertising certain things and persons. The merits of certain baking-powders, disinfectants, water-closets, ventilating cowls, etc., etc., are set forth by certificates of analyses and tests given by Professor So-and-so, and the preparation of such certificates is becoming a rather lucrative profession. While many of these certificates and elaborate puffs, in the shape of formal papers, are prepared by men who are so entirely unacquainted with scientific methods that they betray their ignorance and the mercenary motives which actuate them in almost every sentence, there are a few who possess enough knowledge of chemistry and physics to avoid making gross blunders, and are yet not over-scrupulous in the use which they will make of their knowledge if a sufficient pecuniary consideration be presented.

"It is true that such men are rare, for scientific training fosters the love of truth, and the amount of patient work which it demands is such as to have a strong tendency to secure the survival only of the fittest, which, in this case, means those who will make an honest and proper use of the knowledge they have obtained. Nevertheless, a man *may* be a scientific man, and, at the same time, very shaky in his morals, and such men are very dangerous. There is comparatively little danger, however, from the professional certificates, seeing that it has now come to be generally understood that such certifiers convey really reliable information rather with regard to the character and pecuniary necessities of the men who make them than in regard to the articles to which they relate."

DEFOE UPON THE PLAGUE IN LONDON.

The great plague of London began in December, 1664, and continued in some measure till September, 1666, when the great fire put a stop to it by burning up the foul matter upon which it fed and throve. Meantime from 68,000 to 100,000 persons had fallen victims. Despite the fact that fires were kept burning for three days, with the view of somehow purifying the air, yet the sanitary science of the day consisted chiefly in isolation rather than in disinfection. Defoe's account of the scourge, while generally held to be in part imaginative, yet presents us the most vivid account of it we have, and by contrast is very suggestive of the wholly different plan upon which the officers of public health proceed at the present time when epidemics are present or are threatened. We reproduce the classic account already, doubtless, familiar to many of our readers: —

"It was now the beginning of August, and the plague grew very violent and terrible in the place where I lived; and Dr. Heath coming to visit me, and finding that I ventured so often out in the streets, earnestly persuaded me to lock myself up, and my family, and not to suffer any of us to go out of doors; to keep all our windows fast, shutters and curtains close, and never to open them; but first to make a very strong smoke in the room, when the window or door was to be opened, with rosin and pitch, brimstone and gunpowder, and the like, and we did this for some time; but as I had not laid in a store of provisions for such a retreat it was impossible that we could keep within doors entirely. And here I must observe again that this necessity of going out of our houses to buy provisions was, in a great measure, the ruin of the whole city, for the people catched the distemper on these occasions, one of another, and even the provisions themselves were often tainted, at least I had great reason to believe so. However, the poor people could not lay up provisions, and there was a necessity that they must go to market to buy, and others to send servants or their children; and as this was a necessity which renewed itself daily, it brought abundance of unsound people to the markets, and a great many that went thither sound brought death home with them.

"It is true people used all possible precaution. When any one bought a joint of meat in the market they would not take it out of the butcher's hand, but took it off the hooks themselves. On the other hand, the butcher would not touch the money, but have it

put into a pot full of vinegar, which he kept for that purpose.

"The buyers carried always small money to make up any odd sum, that they might take no change; they carried bottles for scent and perfume in their hands, and all the means that could be used were employed; but then the poor could not do even these things, and they went at all hazards. Innumerable dismal stories we heard every day on this very account.

"Sometimes a man or woman dropped down dead in the very market, for many people that had the plague upon them knew nothing of it till the inward gangrene had affected their vitals, and they died in a few moments; this caused that many died frequently in that manner in the street, suddenly, without any warning. Others, perhaps, had time to go to the next bulk or stall, or to any door or porch, and just sit down and die, as I have said before. These objects were so frequent in the streets that when the plague grew to be very raging on one side there was scarce any passing by the streets, but that several dead bodies would be lying here and there upon the ground; and in those cases the corpse was always left till the officers had notice to come and take them away, or till night, when the bearers attending the dead-cart would take them up and carry them away. Nor did these undaunted creatures who performed these offices fail to search their pockets, and sometimes strip off their clothes, if they were well dressed, as sometimes they were, and carry off what they could get."

THE PATHOGENIC MICROBES OF GONORRHŒA.

THE *Medical News* (August 16th) remarks upon this subject that the gonococcus which was discovered in 1879 by Neisser is discussed in a recent number of the *Nordiskt Medeinskt Arkiv* by Dr. Edward Welander in an elaborate article, in which he concludes that they are characteristic of the disease. His observations are to the following effect:—

The gonococcus is always found in groups, never in chaplets; it is seen in the interior as well as at the exterior of pus-cells, frequently in large groups upon the epithelium, and, besides, in a free state in the secretion. The proofs that they are the pathogenic microbes of blennorrhagia are, according to Welander, that he has found them in one hundred and twenty-nine cases of acute, and in fifteen cases of chronic blennorrhagia, in the male, and in the purulent urethral secretion of forty-nine females, while he has not found them in other secretions; in twenty-five cases of blennorrhagia in all of which the gonococcus was found, he ascertained the persons who communicated the disease, and in them, too, the gonococcus was present. Further, inoculation with secretions which did not contain the gonococcus gave negative results, while blennorrhagia followed those cases in which purulent matter containing the gonococcus was used. Still, the scientific proof is wanting, for the few culture-experiments that have been made are incomplete, or discredited; and so far the cultivation of the gonococcus has proved exceedingly difficult.

In the treatment various antimicrobic remedies have been tried, such as carbolic acid, corrosive sublimate, and iodoform, but the results have not been satisfactory. Welander regards an abortive treatment during the first two or three days as quite proper, and his method is first to cleanse thoroughly the anterior portion of the urethra, chiefly the navicular fossa, with cotton and forceps, thus removing a quantity of epithelial cells with the gonococcus in or upon them, and then cauterize with a solution of nitrate of silver.

So far, it seems that the discovery of the gonococcus has not helped the treatment of blennorrhagia; but it certainly is a great gain to be able to say positively when the contagiousness of the disease has ceased, and when, for example, a man may enter married life safe from the danger of communicating disease to his wife, and thus making her suffer for his sins, giving her not only different forms of intra-pelvic inflammation, but, according to Dr. Noeggerath's views, making her sterile. In medico-legal cases the discovery may prove of the greatest importance. Thus in cases of leucorrhœa in children, against whom it has been charged that rape had been attempted, and disease thereby communicated, the absence of the gonococcus in the vulval or vaginal discharge would at once disprove the charge.

As an incidental practical point, Welander suggests that the oculist may be enabled, by determining the presence or the absence of the gonococcus, to ascertain the nature of a purulent inflammation of the conjunctiva.

MALE HYSTERIA.

THE subject of hysteria in males has lately been brought prominently before the Berliner Medicinische Gesellschaft, says the *Medical Times*, August 9, 1884. A prolonged discussion upon some of the points raised served to show very clearly that the nature and origin of the phenomena so frequently grouped together under that convenient title, are as far as ever from any clear and comprehensible definition. The constant association of hysteria with affections of the uterus, or indeed of any single organ, has long since been disproved, but its frequent association with disease or disordered function of some of the viscera, is clearly shown by many recorded cases. It is only of recent years that the occurrence of hysteria in males has been fully recognized, and the proportion of male to female cases formerly given by Briquet as 1 to 20, is probably somewhat below the mark.

Heredity is a marked feature in these cases, and there is usually a history of nervous irritability in childhood. The period of youth and puberty is the most common time for hysterical phenomena in males, whereas in women there is no period of life exempt from the liability. In his paper on the subject Herr Mendel relates some typical cases, and points out that in some instances a kind of dual existence appears to be present in which the patient may be in perfect health with intervals of hysterical disturbance of the nervous system, the memory in each state retaining no impressions of the events taking place in the other. He draws a marked distinction between hysteria and hypochondriasis. In cases of the latter class, the patient seeks out a cause for his discomforts, and fixing his mind upon the one point, cannot be reasoned or persuaded out of the truth of it, no matter how absurd and inconsistent it may be. The hysterical patient on the other hand exhibits a greater variety of functional disorders, is much influenced by his surroundings, and

gives every evidence of nervous instability. Hence the rapidity with which hysterical cases may be cured when entirely removed from old associations and the sympathy of relatives. Among the complex symptoms characteristic of hysteria, is that of local pain. Until recent years this local pain has generally been believed to be pelvic and to be associated with the ovaries.

Many cases, however, were cited in the debate on Herr Mendel's paper in illustration of the fact that such painful spots may also be found elsewhere. Pain localized in the right ovarian region was found to persist unaltered in a case in which the ovary and a tumor connected with it had been removed by Herr Landau, and hence it could not be due to direct local causes. In his remarks upon the case, however, the operator expressed belief that the pains are essentially to be regarded as forms of visceral neuralgia, having some peripheral origin, most probably in the genital apparatus. In an interesting case related by Herr Senator, two painful spots were discovered, symmetrically situated over the parietal bones, in a boy who exhibited very marked hysterical symptoms. Pressure on these spots, even during sleep, at once set up violent crying and struggling. The case was rapidly cured by isolation. The relation of these painful spots to the condition of hemi-anæsthesia in women is not as yet determined, but a few cases have been recorded by Remak and Landau, in which a bimanual examination of the ovary of the affected side proved the organ to be exquisitely tender. In one instance, with similar symptoms, the painful spot was localized in a movable kidney.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 16, 1884.

Cities.	Estimated Population.	Reported Deaths in each.	Deaths under Five Years.	Percentage of Deaths from				
				Infectious Diseases.	Consumption.	Diarrhœal Diseases.	Whooping-Cough.	Diphtheria and Croup.

Deaths reported 2979 (no reports from New Orleans and Buffalo): under five years of age, 1573; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 1037, diarrhœal diseases 714, consumption 304, lung diseases 143, diphtheria and croup 85, whooping-cough 64, typhoid fever 55, malarial fevers 29, scarlet fever 29, measles 28, cerebro-spinal meningitis 16, erysipelas eight, puerperal fever seven, small-pox one, typhus fever one. From *typhoid fever*, Philadelphia 12, St. Louis 11, Boston six, New York and Chicago five each, Brooklyn and District of Columbia two each, Milwaukee, Providence, New Haven, Charleston, Lowell, Holyoke, New Bedford, Chelsea, Brockton, Newburyport, Andover, and Stoneham one each. From *malarial fevers*, New York and St. Louis 10 each, Baltimore six, Brooklyn two, Charleston one. From *scarlet fever*, Philadelphia and Chicago five each, St. Louis four, Boston and District of Columbia three each, New York, Brooklyn, and Baltimore two each, Pittsburg, Lowell, and Cambridge one each. From *measles*, New York 12, Chicago eight, Brooklyn three, St. Louis two, Philadelphia, Pittsburg, Milwaukee, and Cambridge one each. From *cerebro-spinal meningitis*, New York three, Philadelphia, Cincinnati, Newburyport, and Fall River

two each, Chicago, Boston, Cambridge, Springfield, and Salem one each. From *erysipelas*, New York five, Boston, Baltimore, and St. Louis one each. From *puerperal fever*, Brooklyn two, Philadelphia, Boston, Milwaukee, Nashville, and Charleston one each. From *small-pox*, Philadelphia one. From *typhus fever*, Cincinnati one.

Cases reported in Boston: scarlet fever 50, typhoid fever 20, diphtheria eight, measles three.

In 111 cities and towns of Massachusetts the total death-rate for the week was 19.68 against 20.44 and 19.11 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending August 2d, the death-rate was 23.3. Deaths reported 3909: acute diseases of the respiratory organs (London) 198, diarrhœa 689, measles 109, whooping-cough 76, scarlet fever 74, fever 48, diphtheria 21, small-pox (London 11, Liverpool, Hull, and Sunderland two each, Sheffield 1) 18. The death-rates ranged from 12.7 in Huddersfield to 34.6 in Preston; Blackburn 23.6; Bradford 21.7; Leeds 24.4; Leicester 28.7; Liverpool 28.9; London 22.9; Manchester 27.5; Nottingham 24.4; Sheffield 2; Sunderland 22.4; Wolverhampton 23.3. In Edinburgh 15.59; Glasgow 24.5; Dublin 23.0.

The meteorological record for the week ending August 16th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM AUGUST 16, 1884, TO AUGUST 22, 1884.

BIRMINGHAM, H. P., first lieutenant and assistant surgeon. Granted one month's leave of absence. S. O. 162, Department of the Missouri, August 12, 1884.

WILSON, GEORGE F., first lieutenant and assistant surgeon. Relieved from duty at Fort Walla Walla, W. T., and to take station at Vancouver Barracks, W. T. S. O. 120, Department of the Columbia, August 13, 1884.

WOODWARD, J. J., major and surgeon. Died August 17, 1884.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING AUGUST 23, 1884.

RIXEY, P. M., passed assistant surgeon. Orders to U. S. S. Lancaster revoked. To continue on special duty.

MARTIN, C., medical director. To be retired August 21, 1884.

HEYL, T. C., surgeon. Detached from U. S. S. Independence, ordered to U. S. S. Adams.

AYERS, J. G., surgeon. Detached from U. S. S. Adams, placed on waiting orders.

CURTIS, L. W., assistant surgeon. Detached from U. S. S. Adams, placed on waiting orders.

STEPHENSON, F. B., passed assistant surgeon. Detached from Navy Yard, New York, ordered to C. S. S. Bache.

DERR, E. Z., passed assistant surgeon. Detached from C. S. S. Bache, placed on waiting orders.

OBITUARY. DR. JOSEPH JANVIER WOODWARD, U. S. A.

SURGEON WOODWARD, major and brevet lieutenant-colonel, was born in Philadelphia in 1832. After pursuing his academic course in that city, he was graduated in medicine from the University of Pennsylvania in 1853. He practiced medicine in Philadelphia until he was appointed an assistant surgeon in the army, August 5, 1861. He served with credit and distinction through the war of the rebellion, not only as concerned the performance of his duties to the government, but also with regard to the advancement of his profession. He recorded observations on camp dysentery and on typho-malarial fever, which were of a nature to throw positive light upon many difficult questions connected with those affections and their management in armies; his original work in microscopy, and particularly in photomicrography, after the termination of the war, was such as to give him a world-wide reputation. His most lasting monument, however, will be the excellence of the literary work done by him, in conjunction with the late Surgeon Otis, in preparing the early volumes of the Medical and Surgical History of the War of the Rebellion. Not only the medical corps of the army, but the profession at large, has sustained a serious loss in the death of Dr. Woodward.

Dr. Woodward had been ill for some months, and his death, while not altogether unexpected, has cut short a brilliant career at a comparatively early age.

A CASE OF HOMICIDE BY A WOUND OF THE VULVA.[1]

BY F. W. DRAPER, M. D., OF BOSTON,
Medical Examiner.

"When deeply incised wounds are inflicted upon the genital organs of either sex, the fact of their existence in such a situation at once proves willful and deliberate malice on the part of the assailant. Accident is wholly out of the question, and suicide is improbable except in cases of confirmed idiocy and lunacy."[2] These emphatic words of Taylor will serve as an appropriate introduction to the following notes of a case whose presentation is justified by the fact that it is an interesting example of a very rare form of homicidal violence.

The chief participants in the affair to be related represented a low grade of city life and morals. Michael O'Neil, the convicted assailant, and his wife, Hannah, the victim, occupied a tenement of three rooms, so wretchedly furnished and appointed as scarcely to merit the name of human habitation. Intemperate, improvident, and ignorant, they lived here in wretched squalor, without apparent hope or desire for better things, and showing to their two young children a wicked example of shameless degradation. In such a home the mother came to her death under the following circumstances: —

During the afternoon and evening of Sunday, December 10, 1882, O'Neil and his wife, with two men, named Haley and Ryan, indulged freely in liquor in O'Neil's kitchen. The woman entertained her guests sometimes with songs, sometimes with loud disputes with her husband. In the course of one of these wrangles, O'Neil forcibly informed his wife that if she carried out her expressed intention to place one of their children in a public institution, he would "fix her for it." The carouse continued till after midnight, and the recollection of the two visitors concerning what transpired in the later hours of the evening was naturally vague and unreliable. But it is quite well established by the testimony of Haley, confirmed by that of an officer who passed by the house at midnight and heard Mrs. O'Neil singing, that between twelve and one o'clock Ryan went to bed on a mattress laid on the kitchen floor, while, a little later, Haley shared with O'Neil, his wife, and their two children his host's only bed, the woman lying across the foot of the bed and the children in the middle. What transpired during the remnant of the night could not be fully established in evidence. The occupant of the kitchen floor admitted that he was too intoxicated to be aroused by anything that occurred. Haley testified that some time in the night, while it was still dark outside, he was awakened by one of the children crying for her mother; to his question where the mother was, the reply was that she had gone out. Haley and the two children were the only occupants of the bed at this time, O'Neil and his wife having disappeared. Haley went to the kitchen to get a drink of water, and there he saw Ryan lying on the mattress; and O'Neil, dressed and apparently asleep, at full length, partly on the mattress and partly on the floor. After satisfying his thirst he returned to bed and went to sleep. Some time later he was awakened by O'Neil getting into bed. Haley asked O'Neil where Hannah was; O'Neil replied that he did n't know, he supposed that she was in the other room, that she was all right and would look out for herself. Haley then fell asleep and knew nothing more till the milkman knocked at his usual hour, between five and six o'clock. That disturbance having passed over, Haley took another nap lasting, as he estimated, about half an hour, and was next aroused by O'Neil leaving the bed; he himself arose also and went to the kitchen while O'Neil passed into a small, unfurnished room adjoining the bed-room. In a moment O'Neil shouted to Haley to come and help him, that Hannah was stiff with cold; going to his aid, Haley found O'Neil in the act of raising his wife from the floor. Her only apparel consisted of a chemise and stockings, the rest of her clothing being in a pile at the foot of the bed on the bed-room floor. The two men lifted her up from the floor and carried her to the bed. As they did so, O'Neil noticing blood on his wife's chemise and person, exclaimed, "Oh! my God! look at the blood!" He quickly covered her with the bed clothing, then said, "She must have done something to herself and I 'll be blamed for it." Haley saw then that the woman was dead, and he said to O'Neil that his best course was to notify the police at once. O'Neil washed his hands, talking much meanwhile about his inability to bury his wife, as he had no money. Ryan was now awake and joined Haley in advising O'Neil not to go to work, but to report the affair forthwith at the nearest station-house. This counsel was not taken, but O'Neil left his house and went to the wharf where he was employed. Later in the morning he called upon some of his wife's relatives (her mother and brother) to notify them of her death. He told the mother that "Hannah had done something to herself so that she should n't have any young ones," intimating, as the mother understood him, that an attempt to procure an abortion was the cause of the death. To the brother he offered still another explanation, that she died "in one of her curious spells," and that he was afraid that he would get into trouble about it.

Meanwhile the police had received information of the woman's death, and the case came at once to the writer's notice for his investigation. I found the rooms in the possession of two officers who had O'Neil and Ryan under detention pending the inquiry. O'Neil's statement was that his wife Hannah went to bed about ten o'clock the previous night. After a while he and Haley went to bed in the same bed with her and the children, his wife lying across the foot of the bed. Some time in the night, when it was he did not know, Hannah left the bed. About twenty minutes past six he was awakened by Haley, who asked him where his wife was. He looked about and found her lying on the floor of the inner room, unconscious, cold, and breathing slowly. He put her into bed and left her. He explained his abandonment of her in that low condition by declaring that he supposed her to be playing one of her old tricks of getting on the floor when she had been drinking and avowing that she was going to die. He denied all knowledge of what had occurred to her in the night, and when his attention was called to the presence of blood on her clothing,

[1] Read at the annual meeting of the Massachusetts Medico-Legal Society, June 10, 1884.

[2] Taylor's Principles and Practice of Medical Jurisprudence, i., p. 677.

he said, somewhat excitedly, "If anything 's happened to her, she 's done it herself."

I found the woman's dead body lying upon its right side in a natural posture, at the front of the bed, fully covered with the bed clothing. It was still (at half-past nine in the morning) appreciably warm; rigor mortis was present in the elbows and knees. The only personal apparel was, as already mentioned, a chemise and stockings. The lower and posterior part of the chemise was saturated with blood; and the external genitals, the nates, and the upper part of the thighs, front and back, were blood-stained. The source of the hæmorrhage was not discovered at this time.

Proceeding to inspect the adjacent unfurnished room, where the woman had been found before her removal to the bed, I saw an ordinary, medium-sized wash-tub in the middle of the floor, containing fluid and clotted blood to the amount of four quarts. On the floor, between this tub and the corner of the room nearest the door of entrance, there was a blood stain measuring thirty inches by fifteen inches, with fresh, thick clots upon it. Lying at one side of this stain were an old dress skirt and an apron much soiled with blood. Careful examination of the floor of the bed-room and of the kitchen (all the floors were bare) failed to detect any blood stains in addition to the one above described.

The autopsy was made in the afternoon of the same day, or, as nearly as could be estimated, about nine or ten hours after the death. Omitting unessential details, the following appearances were disclosed: —

The body was that of a stout, strong, though very untidy woman, apparently in vigorous health at the time of her death. There was marked pallor of the surface except upon the right side of the neck and thorax, where patches of livid discoloration corresponded with the dependent part of the body as it lay, after death, in bed during the cooling stage. There were small ecchymoses in the following situations: above the right breast, on the front of the left arm, on the front of the right wrist, just below the bend of the right elbow, on the outer side of the left forearm, on the inside of the right thigh, and on the outer side of the left knee. Along the upper surface of the lower lip, just within the dermal border, there was a broken line of narrow ecchymoses, suggesting that the lip had been tightly compressed between the teeth.

The upper part of the vulva was the seat of the only lesion from which the hæmorrhage, previously mentioned, could have proceeded. This lesion, as the specimen exhibited shows, was a wound with regular, clean-cut, slightly curvilinear edges, one inch long. Its upper extremity was immediately below the clitoris, in the middle line of the vestibule or space between the clitoris and the urethra. It took a direction downward and outward, curving slightly to the left, its lower end being a little to the left of the meatus urinarius. It was half an inch deep at the deepest point. Its course from the surface inward was not direct, or parallel with the antero-posterior plane of the body, but there was a slight beveling from the left toward the right. In a wound so superficial and limited it was impossible to demonstrate the vessels involved in the incision, but the arteries most exposed to division were the terminal branches of the right internal pudic and of the inferior vesical.

The internal examination discovered nothing noteworthy or abnormal beyond the marked anæmia of all the organs and tissues. The stomach contained half a pint of undigested food. The womb and its appendages were healthy. The mucous membrane of the uterine cavity was slightly reddened, and the right ovary contained a typical corpus hæmorrhagicum of menstruation. The vagina showed no trace of blood. The brain was healthy. The exsanguine state of the body was the single striking feature which the examination revealed.

The autopsy having thus conclusively determined the cause of the death to have been hæmorrhage from a wound of the vulva, the next and equally important stage of the inquiry had for its object to decide the manner in which the wound was received.

Was the wound an accidental one? Nothing occurred in the entire course of the investigation to lend support to such a view. A moment's reflection upon the situation of the lesion will convince one that an accidental injury at that part of the vulva is hardly to be thought of as possible. The nates, the perinæum, the fourchette, and the posterior portions of the labia majora are the regions, if any, which receive accidental violence, while the neighborhood of the clitoris could be the seat of a wound by casualty only upon the supposition of the most extraordinary posture of the body in its relation to the wounding instrument. This wounding instrument, moreover, was not discovered in the room with the blood, and the absence of blood stains elsewhere in the dwelling indicated clearly that the entire affair had its scene in this bare apartment. Finally, it is scarcely credible that a woman, injured severely, and aware that she was becoming exhausted by profuse hæmorrhage, would suffer herself to bleed to death rather than to call her husband or her female neighbors to her help. It did not appear that any hint of her distress came to any one until she was found in the morning lying in a pool of her own blood; and this failure to summon assistance is a controlling objection to the theory that an innocent casualty caused the death.

Was the injury inflicted by the woman herself with suicidal intent? Her husband so asserted, but his assertion had no support in the facts or the probabilities of the case. Experience has shown that attempted suicide by mutilation of the genital organs is a very rare occurrence, and the recorded instances are confined almost wholly to the subjects of insanity and idiocy. The person bent on self-destruction does not usually take half-way measures, or inflict upon himself injuries whose issue seems to him clearly to be open to doubt. The surgeon and the anatomist know that wounds of the vulva are particularly grave because of the vascularity of the parts and the consequent danger of alarming hæmorrhage; but no one could seriously suppose that an ignorant woman, representing the lowest grade of intelligence, would select her vulva for a suicidal wound, when a cut across her neck or a thrust into her breast offered a much more accessible and certain passage to death. The wound itself, aside from its situation, offers some difficulties to the theory of suicide, for its dimensions, its depth, especially its direction, are not easily explicable upon the supposition that the woman's own hand held the knife.

But it is clear, without regard to these somewhat theoretical considerations, that certain indispensable data are wanting if we would establish that the wounding was done by the patient herself. Obviously a

weapon or some sharp instrument was required for its accomplishment. No such weapon or instrument was found in the room. If the wounding was done in another room, and the woman then went to the room which was the scene of the hæmorrhage, or if, having cut herself in the latter room, she had then made her way to some other part of the house to hide the weapon or to destroy it, and had then returned to take her seat over the tub to slowly bleed to death, some sign of these journeyings would have appeared in the form of a trail of blood stains on the floor of the kitchen or bed-room or both; and this evidence was wholly wanting.

What, then, is left as a reasonable explanation of the wound, the hæmorrhage, and the death, except that they depended for a cause upon the act of some person other than the deceased? We must admit that all the facts in the case are in harmony with this view, and that nothing inconsistent therewith was developed in the course of the inquiry. The act of violence was not seen, it is true, by any third party; it occurred under circumstances known only to the single surviving participant in the affair, and his lips remain silent.

But it is in just such cases that medico-legal diagnosis has its greatest fascination. In a homicide, the evidence of which is complete through the testimony of eye-witnesses or the confession of the accused, there is but little to attract the medical jurist; his connection with the investigation becomes then a matter of form merely, and assumes relations of secondary importance. It is when the truth has to be sought out by devious channels, when an aggressive defense of a suspected individual puts the burden of proof most heavily on the servants of the State, when circumstantial evidence is the only reliance, and there are in reality two sides to the question, — it is in these exigencies that legal medicine has its greatest opportunity and its chief charm. The Parkman case would have lost half its interest and instructiveness if the janitor or some other person at the medical college had seen Webster strike down his victim. The famous cases of murder by poisoning are absorbing because of the doubts which they admit, and because of the manner in which those doubts are met by the tests of the laboratory, and by the close reasoning of the unpurchased expert. So, applying the ever-safe method of elimination to our examination of this vulval wound, studying its situation and direction, the circumstances which, at some distance, preceded and followed it, the data present, and the not less important data absent, the character and habits of the woman, her conduct with her carousing companions, the behavior of the husband and of his guests before and after the death of the woman, — in fine, considering all that the "view, personal inquiry, and autopsy" supplied as material for a differential diagnosis, and excluding such hypotheses touching the manner of the death as appear manifestly inconsistent with the facts, we are then in a good position to answer affirmatively the question, Was the death by homicide? The identity of the person who inflicted the fatal injury, his motive and his weapon, are matters of remote interest in their relation to the abstract question of the cause and manner of the death. They are almost exclusively within the province of the police detective, and do not concern the medical examiner except as they may supply confirmatory facts to buttress his conclusions. A brief allusion will be made to them in connection with the present case for the purpose of completing the story.

It must have been made plain in what has preceded that from the very beginning of the investigation suspicion fell upon O'Neil, the husband; indeed, he drew it upon himself by his own behavior. If he had been a cooler and less ignorant culprit he would have avoided the mistakes into which his apparent consciousness of wrong-doing led him. No one saw him in the act of injuring his wife, but the readiness, almost the eagerness, with which he tried to throw the blame of her death upon herself, his prompt avowal that he would nevertheless get into trouble on account of it, his retreat from the scene, and his frivolous excuses for doing so, — these turned attention toward him as the probably guilty agent. In harmony with these acts were certain points in direct evidence, such as the testimony that O'Neil left his bed for an interval during the night, and was discovered lying on the kitchen floor, his wife meanwhile missing; and the testimony of a woman up-stairs, that just before four o'clock in the morning she heard O'Neil and his wife quarreling, and was sure she identified the voices. Meagre as was the evidence, it satisfied the court of inquest which found O'Neil accountable, the municipal court which held him on the charge of murder, the grand jury which indicted him for manslaughter, the jury which found him guilty under this indictment, and the judge who sentenced him.

The motive for this crime is wholly a matter of conjecture. We may imagine that O'Neil and his wife, both inflammable in disposition, as the previous evening's events showed, found some cause for a quarrel after their guests had been disposed of for the night. The previous criminal relations of the woman with one of the men then enjoying her hospitality suggests that the use and abuse of the sexual organs may have been the theme of dispute. We may imagine that, as an outcome of the dispute, whatever its subject, O'Neil suddenly resolved to mutilate his wife in a way that should teach her a salutary lesson. It is not necessary to assume that he meant to injure her seriously, far less to wound her fatally; his purpose, probably, was chastisement only. His guests were deep in the sleep of drunkenness, or so appeared, and he himself was sufficiently alcoholized to render him more reckless than delicate in his cutting. We can suppose that the woman, finding herself hurt about her genitals and bleeding freely from the wound, took her seat over a convenient wash-tub, expecting, as one attacked with epistaxis expects, that every minute would see the spontaneous subsidence of the flow. Her husband having been her assailant, she would not call for his help, as she would have done very naturally if either of the other men had injured her. So, bleeding to syncope, as she sat on the tub, she at length fell to the floor, and presently died. Meanwhile the husband, not realizing the extent of his violence, and anxious not to awaken his bed-fellow, sought rest on the kitchen floor, where he was seen by Haley. Later, when all was quiet, and he felt quite certain that he could move about without disturbing any one, he resumed his place in bed, and remained there till the morning brought its sanguinary revelations.

The instrument, like the motive for its use, was almost wholly a matter of speculation. A knife was introduced in evidence at the trial, and the medical witness readily testified that it might have made the

wound of the vulva. This knife was identified as O'Neil's; Haley had seen him cutting tobacco with it during the afternoon of their carouse. It was a knife such as a shoemaker uses for trimming soles; it had a blade about four inches long, which had become somewhat concave at its edge by long use and repeated grinding, but its rounded point was well sharpened. This blade was fixed firmly in a wooden handle. This weapon, if such it was, was found secreted behind a looking-glass in the kitchen, on the morning of the woman's death. It was given by the finder to another woman, who placed it in her stove for safe keeping over night. A fire was made in the stove by a third person, who had no knowledge of the contents of the oven, and the consequent baking and charring destroyed all evidence of blood-stain, if any existed. The person who found the knife testified that it was clean and bright when she first saw it.

But it will be proper to ask if such a wound necessarily implied the use of a knife to produce it. May not the lesion have been a contused wound, the result of a kick, the blow being received in such a direction and situation as to cause a solution of continuity simulating an incision. It is well known that the appearances of a cut may be closely imitated by a smart blow from a blunt instrument upon soft parts overlying bone, and cases are not wanting in which a wound of the vulva produced by a kick or a fall has given rise to grave doubt whether or not a weapon has been used.[1] While admitting the possibility of fatal hæmorrhage from a contused wound of the pudendum, and even granting that a kick with the shod foot might divide the tissues and leave something of the appearance of a cut upon them, it must nevertheless be insisted that the vertical direction of the lesion in the present case, its clean-cut, regular edges, its smooth inner surfaces, the absence of swelling and of ecchymosis in the adjacent parts, are quite strong points of proof that a cutting rather than a blunt instrument was used.

But however wisely or wildly we may speculate upon questions whose solution is difficult or impossible through a want of satisfactory data, the most important feature of the case remains well-founded, as an instructive medico-legal fact, and it is to this that I give the concluding word. This is the material and significant reality that within the space of five hours (taking outside limits of time) a strong, plethoric, and healthy woman bled to death by a wound of the vulva an inch long and half an inch deep. Such an occurrence, if standing alone as one observed for the first time, would be regarded as extraordinary, perhaps as incredible; but it is fortunate in being in accord with similar observations recorded in surgical and medico-legal writings. It is really a typical example of an interesting class. Ogston[2] quotes the case of a woman who died in ten minutes after receiving two wounds about the genitals, one on the left labium and the other at the entrance of the vagina at its upper part; the fact that she was pregnant, and that the vascularity of the parts was thus increased, may have had some influence upon the rapidity of the hæmorrhage. Taylor[3] alludes to the case of a woman, eight months pregnant, who "fell from a chair, which also fell with her. There was hæmorrhage, and she died in a quarter of an hour. The blood had flowed from a wound an inch and a half long, situated between the right labium and the urethra." In another case[4] "a contused wound of the clitoris proved fatal. A woman, aged thirty-six, received a kick from her husband in the lower part of the abdomen while she was in a stooping posture. When seen, in about three quarters of an hour, she had lost from three to four pounds of blood; she was sinking, and expired a few minutes afterward. The wound was at the edge of the vulva, extending along the ramus of the pubes; it was about an inch long and three quarters of an inch deep. The left crus clitoridis was crushed throughout its length." These cases are of use in teaching the medical witness that, whether in the presence of a jury or elsewhere, he should be economical in the use of terms like "impossible," or "incredible," or "inconceivable."

A CASE OF ACUTE HEMIPLEGIC CHOREA; WITH AUTOPSY AND REMARKS.

BY RALPH M. CANFIELD, M. D., AND JAMES J. PUTNAM, M. D.

THE following case is, from several points of view, one of unusual interest: first, as being a typical example of a comparatively rare affection, unilateral chorea in the adult, traceable to a distinct organic lesion in the brain; then, because it is remarkable that this lesion — involving, as it did, a portion of the crus cerebri — did not give rise to paralytic symptoms of more pronounced character; and, finally, because of the points in diagnosis and treatment to which it calls attention.

The patient was a man of fifty-nine years, of large frame, and of robust type. For the past fifteen years he had been quite intemperate, and this habit had grown upon him, until for the past eight months he had taken daily six or eight potions of best rye whiskey, with now and then a spree of two or three days' duration. Otherwise his life had been an average one, and his family history is one of peculiar longevity, with no cerebral or other marked diseases. His wife says that for a year past he has been more irritable than formerly.

For some weeks previous to the onset of serious symptoms his family had noticed choreic movements in his right arm and leg, and for the last week a slight dragging of the leg. In ascending stairs, however, he had used his feet equally well, so that there could not have been any paralysis in consequence.

On August 5th his wife came to ask medical advice, and gave the above history, adding that the movements had become more violent and constant, but that they ceased entirely during sleep. The previous night, however, sleep had been impossible. The patient was ordered twenty grains each of bromide of potassium and hydrate of chloral, which gave him a comfortable night. The next day he was examined carefully and the following condition noted, which remained without essential change until shortly before his death: —

The right arm and leg were found to be in violent and constant motion of a distinctly choreic type, but involving the muscles of the larger joints — hip, shoulder, etc. — even more than those of the smaller.

The face was apparently still, but the articulation was nevertheless somewhat thick. At times the right

side of the face seemed to move less well than the left, but the tongue was protruded straight. The movements increased in violence when any attempts were made to use the limbs, and although the patient declared himself unable to check them by voluntary effort, yet it was striking to observe how, if the arm were drawn quietly to the side and the patient strictly enjoined to lie still and close his eyes, the movements would cease for a moment and the patient sink into a half sleep.

No diminution of gross strength could be observed in the affected arm or leg. The knee and ankle reflexes, which were normal on the right side, were wholly absent on the left. The plantar, cremaster, and umbilical reflexes were absent on both sides. The sensibility to the prick of a pin seemed less over the affected side, though this may have been due in part to the engrossing influence of the movements. No finer tests were possible. The patient complained of no pain or sense of numbness, but said the skin felt sore or raw, as if flayed, over the right arm and leg.

His intellect was slightly clouded, but at times, when aroused, he seemed quite rational.

The surface temperature of the right arm and leg was markedly higher on the right side, but perhaps not more so than could be accounted for by the constant motion. Still, these parts had a turgid feel, and the skin over them, as well as that over the right side of the face, was slightly reddened. There was no change in the acuity, or field of vision, nor in the movement of the eyes. Pulse full and strong; somewhat tense. Respiration normal. Heart not enlarged; sounds normal.

In spite of the movements the patient was able to walk across the floor to the bath-room without help. Micturition voluntary.

The temperature at this period was normal, or slightly elevated (99.5° F.); but in the last days of the patient's life it ran up to 102° F., the pulse and respiration becoming at the same time rapid and feeble.

The bromides, chloral, morphia, and valerianate of zinc were given in full doses, at different periods, to check the movements, but as they failed to do so satisfactorily the fluid extract of conium was substituted. Sixty minims of this were given the first day, and the dose was gradually increased until, on the third day afterward, he took six drachms in twenty-four hours. Then for the first time the characteristic effects were seen, namely, paresis, first of the eyelids, soon afterward of the arm, and later of the leg. The conium was then discontinued for the time.

The next day he seemed quite comfortable and took a generous diet, including milk punch, beef peptonoids, eggs, chicken, etc. The involuntary movements had almost ceased, and he slept quite naturally during the night and somewhat during the day.

On the following day the movements reappeared. The conium was again commenced and carried up to full doses with but very little, if any, effect, and six days later (August 19th) Fowler's solution was substituted. Twenty-four minims in the twenty-four hours were given at first, and the dose was gradually increased until, on August 22d, he took forty-eight minims, which produced the characteristic symptoms of puffing of the lids, etc. The effect of this seemed to be beneficial, but it had been evident for some time that the patient had been failing in both mind and body, and was now nearing his end.

On August 23d the pulse became small and weak, the temperature began to go up, the respiration became frequent and hurried, and his exhaustion increased rapidly. The stimulants were increased, but the system failed to respond. He became semi-comatose, and died August 25th, having been unconscious for the previous twenty-four hours.

On the day before his death the respiration numbered fifty-two and the temperature was 102° F. On the morning of his death the respiration had reached ninety-two.

The autopsy was performed forty-eight hours after death. As the weather was warm the abdominal organs had become somewhat discolored and decomposed, rendering it difficult to affirm the presence or absence of finer changes of structure in them. The brain, however, was well preserved, and we shall confine our report to that, as being manifestly the seat of the disease.

Calvaria rather dense, but of even thickness and without erosions; dura unusually adherent in spots.

Dura normal, sinuses nearly empty of blood.

Pia not at all, or but slightly, opaque; contains a moderate amount of fluid in its meshes. No marked atrophy of convolutions. Vessels contain but little blood. About one ounce of nearly clear fluid left in skull after removal of brain.

Vessels at base of brain excessively atheromatous, the larger ones not collapsing at all when cut across. The lumen of some of the vessels is materially encroached upon by this degenerated tissue, which is separable in large flakes. All exposed vessels examined for plugging, but none found.

Ventricles of brain essentially empty.

Cut surface of hemispheres pale; ciings to section knife; no puncta cruenta; gray matter everywhere ill-defined.

Parallel frontal sections[1] were next made through the brain from before backward at intervals of about half an inch or less. No lesions were seen until the cut passing through the base of the anterior transverse convolution and the anterior extremity of the nucleus lenticularis was reached.

Scattered over the cut surface of the latter ganglion, in the *left* hemisphere, were several minute, brownish spots of softening, two or three millimetres in diameter, not involving the capsula interna. In the corresponding ganglion of the *right* hemisphere, one or two similar spots were seen, and another, somewhat larger, in the white substance just above the nucleus lenticularis, and just at, or outside, the limits of the capsula interna, strictly speaking.

One or two similar spots of softening were seen on several subsequent sections, but they were confined to the nucleus lenticularis except at one spot, in the left hemisphere, where a portion of the capsula interna adjacent to a spot in the upper edge of the nucleus lenticularis seemed a little softened. Some of the spots were rather linear than round, and evidently marked the course of vessels, although no distinctly thrombosed vessel were seen.

Up to this point both hemispheres had been nearly equally affected (the left, to be sure, the most), but the next and largest lesion involved the left side alone. This was first seen on the cut dividing the crura cerebri just after their emergence from the brain, as a dark brown spot about two millimetres in diameter, at the

[1] After the manner of Pitres.

junction of the middle and outer third of the pes cruris, a little below the substantia nigra. Careful examination subsequently showed that this spot was the lower edge of a mass of somewhat softened and partially necrosed tissue, of the size of a large pea, though of more oval shape, and with its long diameter passing obliquely inward and upward through the inner half of the crus. The substantia nigra was involved, and the neighboring portions of the tegmentum cruris, but the lesion did not penetrate the thalamus opticus, which appeared healthy on all sections. The only ganglionic matter involved besides the substantia nigra was (probably) the so-called ganglion of Luys. In other words, this collection of diseased tissue lay in the inner half (mainly in the inner third) of the crus cerebri opposite the posterior portion of the thalamus. It involved the substantia nigra, together with the pes cruris beneath, to the depth of five or six millimetres, and the tegmentum above almost to the centrum rubrum. It was bounded behind by a (frontal) plane drawn through the posterior edge of the corpus candicans, and in front by another plane nearly one centimetre in advance of this.

The diagrams given by Meynert at page 694 of Stricker's Handbook of Histology (American edition), and by Wernicke at pages 64 and 66 of his Lehrbuch der Gehirnkrankheiten, indicate very well the level of the lesion.

Cerebellum, pons, and medulla oblongata were normal, except that, like that of the rest of the brain, their tissue was very anæmic.

Microscopic examination of the softened tissue in the crus, as well as of the minute spots in the nuclei lenticularis, showed them to consist of disintegrated brain tissue, masses of granular bodies and granules of free fat, and occasional crystals of hæmatoidine. The walls of the smaller vessels contained masses of pigment, and their sheath was often crowded with granular bodies. The cells of the substantia nigra in the affected part were also seen to be in every stage of degenera tion. Some of them were still recognizable from their pigment, while others had evidently lost their pigment, though still of characteristic size and shape.

The mode of onset and the progressive course of the disease in this case, — the clouding of the mental functions, the disappearance of the reflexes, the slight unilateral impairment of sensation and motion, — marked it, even before death, as being probably of organic origin, and to be ranked with the so-called pre- and post-hemiplegic disorders of movement. Nevertheless, before inquiring into the physiological pathology of the chorea in its relation to the lesions actually discovered, it is important to bear in mind that equally violent and exactly similar movements are capable of coming on, and lasting for long periods, without the influence of any gross lesion whatever.[1]

A knowledge of this fact ought surely to make us careful *what rôle* we assign to the hæmorrhages and softenings that have been observed in cases like that before us, though it does not in the least impair the value of the many observations, which show, on the whole, a remarkable constancy in the seat of the majority of the lesions with which these disorders of movement, *so far as they have been of organic origin*, have been found to be associated.

It is unnecessary to review the history of this subject at any great length.

These disorders of movement were first called attention to by Mitchell, in 1874, and by Charcot at about the same period, under the name of post-hemiplegic chorea, and since then have especially engaged the attention of many observers.

The investigations of Gowers[2] have made it clear that there is a whole family of symptoms of this class, embracing the post- (and pre-) hemiplegic chorea and the athetosis of Hammond, as well as a variety of intermediate forms, characterized by slow or quick, regular or irregular movements, some of them occurring only in connection with voluntary motions on the patient's part, others spontaneous or (as in the present case) only exaggerated during voluntary efforts.

Almost invariably these disordered movements are associated with incomplete paralysis either in the progressive or the regressive stage, but occasionally they occur without paralysis, and in one case a totally paralyzed limb has been reported to be the seat of the spasmodic movements. (Bernhardt.[3])

The different members of this family of symptoms are certainly closely related, since it sometimes happens that in the history of a single case several of these different forms of movement are successively or simultaneously present.

We must wait until more is known of the anatomy and physiology of the central nervous system, and until a larger number of autopsies have been made, before we can satisfactorily discuss the physiological pathology of these interesting phenomena.

Judged from the standpoint of gross anatomy, the bulk of the evidence points to the thalamus opticus and its immediate neighborhood, especially the region supplied by the posterior external thalamic artery, as the favorite seat of the lesion,[4] and here it was found in the case before us, as well as in the similar one recently reported by Greiff. (Vide below.)

Significant as this fact is, however, it cannot be taken as proof that the symptoms are always due to a disordered action of that ganglion, for in other cases the apparently effective lesion has been found in the nucleus lenticularis, the capsula interna, the pons and medulla, the cortex cerebri, and, finally, it has been shown that similar symptoms may occur without any gross lesion whatever (see above), as in the chorea of children.

Although we cannot assert the cause of these symptoms, we can say that the explanation offered by a number of observers (Kahler and Pick, Démange, Greiff,[5] and others), that they are due to a direct irritation of the great motor tracts of fibres running from the brain to the spinal cord, is anatomically and physiologically improbable, and that it has really only its apparent simplicity to recommend it. Were this explanation correct, then lesions of these tracts at any part of their course should have this effect, whereas, in fact, it only follows lesions at or above the level of the medulla oblongata.

This is a significant fact when we remember that these are the lowest stations which contain coördinating arrangements of any complexity. Furthermore, it is

[5] Arch. für Psychiatrie, etc., Bd. xiv., p. 598. This observer reports with great thoroughness a case closely resembling our own both clinically and pathologically.

noteworthy that no experimental excitations below the level of these organs are capable of causing generalized convulsions in animals. (Nothnagel.)

In other words, it would seem that the efficient factor is the irritation, not of the motor tracts of fibres, but of the ganglia lying near them.

It is true that many of the lesions found in these choreiform cases are in such a position that they *might* irritate the motor tracts. This is true also of our case. But so also there are other disturbances which these lesions might, and indeed must effect, and chief among them is the damaging of the associating tracts between the various cerebral centres, with which the direct motor tracts in the cerebral portion of their course are everywhere interlaced. This is, physiologically, almost equivalent to an injury of the centres themselves.

In our opinion, the most natural way of regarding these choreic movements is to suppose them produced in disease by similar means to those which would produce them in health.

There are various coördinating ganglia in the brain which, in health, probably act sometimes together, sometimes separately, in the production of coördinated movements. In disease these same ganglia are also sometimes set in action, but by some other than the normal mode of excitation, and in such a manner that the results of their activity suggest the motion of a machine, of which the parts are out of gear or the balance-wheel destroyed. Why lesions in or near the thalamus opticus should be especially prone to produce this result cannot be explained.

In whatever way the motor-coördinating apparatus is called into this uncontrolled activity, the movements which come to the front are probably those expressing the average mode of activity of the ganglionic masses concerned, that is, they are movements of most habitual recurrence; and it is therefore not remarkable, that cases with different lesions, and with lesions in different localities, should bear a certain likeness to each other. Neither can we agree with Nothnagel in regarding it as improbable that similar lesions should give rise now to slow and regular, now to quick and irregular movements, unless, indeed, we deny that the individual himself makes use of one and the same nervous centres for movements of these different grades, a position which could not be maintained.

The case before us could not, to be sure, be used as an argument against the view of Kahler and Pick and Démange, since the lesion bordered closely on the motor (volitional) segment of the crus cerebri (the middle third), and even encroached on it to some extent. The bulk of the lesion, however, lay partly in the inner third of the pes cruris, partly in the fibres of the tegmentum, and it is this latter part of the lesion which, reasoning from the other cases reported, we suspect to have been the really efficient factor. It is not to be forgotten that there were several very small patches of softening in the nucleus lenticularis. Their influence in the result is problematical; but from the fact that they were present to a nearly equal degree on both sides, it is not probable that they caused the purely unilateral choreic symptoms. Possibly the injury done to the substantia nigra, which receives fibres from the nucleus lenticularis, and discharges others into the pes cruris (Wernicke), may have played its part also in the result.

At all events this case is certainly to be ranged with the now considerable number of those in which the region supplied by the posterior thalamic artery has been found diseased, a fact for which at present no explanation can be given.

THE CASES OF THE SURVIVORS OF THE LADY FRANKLIN BAY EXPEDITION.

BY EDWARD H. GREEN, PAST ASSISTANT SURGEON, U. S. N.

As a preliminary to a medical history of the cases of the survivors of the Lady Franklin Bay Expedition, it is well to give a brief *résumé* of their mode of life at Camp Clay, their quarters, rations, etc., so as to better appreciate the condition in which they were found.

On September 29, 1883, Lieutenant Greely landed with his party at Baird Inlet after thirty days' exposure drifting on an ice-floe. The record left at that time stated the *party was all well*. Having sent an advance detachment ahead, it was found and reported that a *cache* of provisions existed at Cape Sabine (fifteen miles farther to the northward than he was at this time); it was deemed expedient to move the whole command up to that neighborhood, rather than send for the provisions and winter at Baird Inlet. Finally, on October 25th, they moved around to a point between Cape Sabine and Cocked Hat Island (latitude 78° 45′ N., longitude 74° 15′ W.). The site of their winter quarters was sheltered between high ridges of mountains, which screened them in a measure from the northerly and southerly winds. A glacier was situated at the foot of the mountain on either side of them about a mile distant. They constructed a house of loose rock and moss, the walls being three feet in thickness; the roofing consisted of old canvas stretched over a boat; the dimensions of the house were twenty-five feet long, seventeen feet wide, and four feet high, making the cubic air space 1,700 feet. In this the twenty-five members of the party lived all winter, having a cubic air allowance of about seventy feet for each man. The whole party could barely squeeze in and lie at length, two or three being obliged to occupy the same sleeping bag; the effect of this diminished air space will be seen later on. Their hut was but one hundred yards removed from the ice-foot of the Sound, and two hundred yards to the south of them was an artificial lake, from which they drew their water supply by melting ice. As the sea water strained into this lake, they were drinking brackish water all the while.

On November 1st Lieutenant Greely took a careful account of his stock of provisions, and found there was but a whole ration for each man (estimated as an army ration, about forty-six ounces solid food per diem) for forty days. Dr. Pavy and he advised together, and it was with some reluctance that they determined to divide up the rations so as to make them last until March 1st, putting aside from time to time, so that at the end they would still have ten days' supplies left with which to attempt the trip to Littleton Island if the straits were frozen over. Dr. Pavy did not think the party could exist on the ration during the winter, but the common voice was to make it go as far as it would, so each man was given the following daily allowance: —

Meat and blubber	4.33 oz.
Bread and dog biscuit	6.5 "
Canned vegetables and rice	1.4 "
Butter and lard	.75 "
Soup and beef extract	.90 "
Berries, pickles, raisins, and milk	1 "

making the daily allowance for the four months 14.88 ounces. During the winter the following amount of game was secured, which added to their stores: two seals, yielding about 120 pounds of meat; one bear, yielding 300 pounds of meat; eight foxes (four pounds each), and sixty dovekies (Uria Brünnichii), a small bird weighing about a pound.

March 1st found the party intact, with the exception of Sergeant Cross, who died in January with well-marked scorbutic symptoms, the only case of pronounced scurvy that developed; and Hans, their Eskimo hunter, who was lost in his boat while hunting seals early in February. The straits having been kept open during the winter by a succession of violent gales, the attempt to cross to Littleton Island had to be abandoned, and their ration was still further reduced to the following allowance: meat, 6.8 ounces; bread and dog biscuit, 3.2 ounces, — the rest of their stores being exhausted. The stores were divided up so as to last until May 12th. The sun had returned by this time, after an absence of 128 days, and those employed as hunters caught the sea fleas, or shrimp, a small crustacean, one eighth to one fourth inch long, consisting of about four fifths shell and one fifth meat. From one to three ounces of these a day, according to the catch, were allowed in addition to the ration. After the last reduction, the party began to weaken and die off rapidly.

About the 24th of March the whole party was overcome with asphyxia and nearly lost their lives, owing to the atmosphere being surcharged with carbonic acid. They had lit their alcohol stove in the hut to cook a meal, without previously having removed the rags from the vent-hole in the roof; the remaining oxygen of the air was soon consumed by the stove, and the whole party were seized with faintness, vertigo, and dyspnœa. It was with the greatest difficulty they struggled from their sleeping-bags, and stumbled and were helped into the open air, many fainting away and dropping unconsciously after reaching the opening; being poorly clad for a temperature such as prevailed outside at the time (— 46° F.) many were frost-bitten. The after effects of this mishap remained for a long time and weakened many of them.

After May 12th everything like a regular ration was exhausted, and they struggled on as best they could, catching the shrimp (which they boiled), gathering reindeer moss, which, when boiled, yields a mucilage, similar to Iceland moss, and boiling up the seal-skin linings of their sleeping-bags from which a gelatinous moss was extracted. It was not till they had exhausted the supply of moss around the camp that they gathered the black lichen (*crêpe de la roche*) growing on the rocks, and boiled that. Dr. Pavy urged strongly against its use, as he had the authority of Kane and Hayes that when eaten it would produce a diarrhœa which, in their weakened condition, would be fatal. They had no fuel for artificial warmth, and barely sufficient to allow for melting the ice for procuring drinking water and to cook a meal every other day, so that the living temperature of the hut for the winter was from 5° F. to 10° F.

The recognized the fact that the nearest they could approach a state of hibernating, the better were their chances of getting through. Only those employed as cooks and hunters exerted themselves much, and they were given a double ration; the rest of them occupied their sleeping-bags, and slept sixteen to eighteen hours out of the twenty-four. In answer to complaints of hunger, Dr. Pavy's motto was, "*Qui dort, diné;*" which was philosophical, without being filling.

There seemed to be but little acute suffering from the lack of food. It was only after the introduction of food into the stomach that the craving became great. For days they went without food without actually suffering; the deaths seemed to take place finally from heart trouble (*hydrops pericardii*); the feet and face became œdematous; for a day or so the individual would complain of pains over the heart, have a spasm of pain over præcordia, a slight general convulsion, and all would be over. Their chief suffering during the winter was from constipation. Many went eight to ten days without a stool, and one as long as sixteen days; the fæces became so hardened and impacted in the rectum that at each operation they were obliged to dig the fæces out with their fingers, the abdominal muscles being too weak to extrude the mass. Nearly every one would faint, after having a stool, from sheer exhaustion.

When it is considered that for nine months they were on the ration as detailed, had nothing but brackish water to drink, no artificial warmth, living in a temperature of 5° F. to 10° F. for the winter, with a cubic air space of seventy feet per man, the condition in which the survivors were found will not be wondered at. There were but seven out of the twenty-five found alive; these were: A. W. Greely, first lieutenant U. S. A.; Henry Beiderdick, hospital steward; D. L. Brainard, sergeant U. S. A.; Thomas Connell, private U. S. A.; Joseph Ellison, sergeant U. S. A.; Julius Fredericks, sergeant U. S. A.; Francis Long, sergeant U. S. A. The four first mentioned were taken on board the Flagship Thetis, and placed under my care, and with them this paper will principally be concerned.

On landing at the camp, the condition of the party was so desperate that a delay of two hours was necessary to restore them sufficiently to permit their being removed on stretchers to the boats and taken off to the ships. Thomas Connell, private, was "in extremis," was pulseless, unconscious, and unable to swallow, limbs cold, and respirations barely noticeable; auscultating over the heart, the sounds were heard very indistinctly. By propping him up, forcing open the jaws, a teaspoonful of brandy was slowly poured into the back of the throat. The effect of the stimulant was soon noticeable, as a faint pulse appeared at the wrist; in ten minutes he could make an effort to swallow, when more brandy was administered, followed by some warm condensed milk at intervals. The rest of the party were served with brandy, milk, and beef essence, and finally transported to the ships.

The time and space would hardly be allowed me to give more than a brief detail of the cases; and as they closely resembled each other both in symptoms and treatment, I will confine myself to the case of Lieutenant A. W. Greely more particularly, alluding to anything peculiar in the other cases.

June 22d, eleven P. M. A. W. Greely, lieutenant United States army, aged forty. Disease, asthenia. On admission fainted, after being carried below, in the ward-room, and vomited. Administered ammonia spts. aro-

mat. m. x., renewed in ten minutes; placed in the berth; given a teaspoonful of raw fresh beef, minced; his clothes were carefully cut off, and heavy red flannels, previously warmed, substituted.

On examination his body emitted a sickly, offensive odor, as of stale urine; emaciated to a degree. Skin hanging from limbs in flaps; face, hands, and scalp blackened with thick crust of soot and dirt (had not washed or changed clothing for ten months).

Nervous system: Excitable and irritable. At times almost irrational, eyes wild and staring; insists on talking, craving news, and demanding food; complains of no pain.

Digestive system: Tongue dry and cracked; heavy brownish black coat; ravenously hungry; abdominal cavity empty, and lying almost in contact with vertebral column; no movement of bowels for six days; liver, dullness on percussion, confined to right hypochondriac region.

Respiratory system: Respiration 12 per minute; auscultation and percussion reveal no abnormal condition of lungs; vesicular murmur puerile.

Circulatory system: Pulse 52, soft and compressible; auscultation shows marked murmur (blowing) in systole over base of heart.

Integumentary system: Skin cold and clammy, sickly odor emanating from it, shriveled and sallow. Temperature 97.2° F. (under tongue).

Locomotor system: Great muscular waste; unable to move or stand without support. Body, weight 120 pounds. Weight before leaving Fort Conger in August, 1883, 168 pounds.

Urinary system: No specimen obtainable.

Treatment: From eleven P. M. till eight A. M., alternating every half hour, teaspoonful of raw fresh beef, minced, with teaspoonful of milk punch. Enjoined strict quiet. Pulse then rose to 60 per minute, soft. Temperature 97° F.

June 23d. Nervous system: Mind still active and restless; compelled to allow him some home letters to read, after which became more composed; has not closed his eyes; talks rationally, but shows loss of memory, as often repeats himself.

Digestive system: Had a small, highly offensive stool; felt quite faint afterward; passed considerable wind from bowels; abdomen tympanitic; tongue still dry and coated.

Circulatory system: Pulse slightly stronger, 60 per minute. Respiration 12 per minute.

Integumentary system: Same offensive odor. Temperature: A. M. 97.8° F.; P. M. 98° F.

Locomotor system: Still unable to raise himself up without help; muscles very soft and flabby. Some stiffness and pain in the joints.

Urinary system: Urine passed in twenty-four hours. 1630 cc., specific gravity 1014, acid, highly albuminous ($\frac{1}{10}$ tube).

Treatment: Continue raw fresh beef at intervals of an hour with a raw onion, finely cut up, added; also milk punch one ounce every two hours; no medication.

June 24th. No sleep; mind more tranquil, but too active; great desire to talk and read; less persistent in demanding food; complains of soreness in limbs; tongue presents a moister appearance; bowels slightly distended with gas; no stool; pulse 62, not so thready; heart sounds stronger, still a pronounced anæmic murmur; blood examined microscopically shows large increase of white corpuscles, at first the field ($\frac{1}{10}$ objective) appeared filled with the nucleated corpuscles; close examination showed the proportion to be about one to twenty red; the red corpuscles show but little disposition to cohere and run into "*roleaux*," and lacked the distinctive biconcave disk shape; edges full and round (not ragged); urine passed in twenty-four hours, 1660 cc., highly albuminous; no casts revealed by microscope; skin clammy, dirty mottled yellow; temperature: A. M. 97.6° F.; P. M. 98° F.; muscles sore; slight œdema of hands and ankles.

Treatment: Sponging with tepid water, afterward briskly rubbed with flannels and a little lin. sapo.; small quantity of oatmeal, thoroughly boiled, four ounces allowed in morning; beef essence Liebig's ℥i. in hot water every four hours; continue scraped beef and onion; no medication.

June 25th. Marked improvement; mind more tranquil; talks quietly without excitement; slept two or three hours naturally; awoke refreshed; tongue beginning to clean; had a large, dark semi-solid stool, odor offensive in the extreme; evidently but little biliary secretion poured into alimentary canal; pulse 65, some strength; respiration 14, principally costal; skin losing clammy feel; emanations still sour and offensive from it; temperature: A. M. 98.2° F.; P. M. 98° F.; muscles sore, ankles puffed.

Treatment: Shampooing muscles with dry cloths; no change in diet; no medication.

June 26th. Allowed to sit up in bed and read a little; slept six hours soundly during the night; mind tranquil; has a loss of memory of words; tongue cleaning, still heavy coat at the back; bowels moved twice; stool pitchy and offensive; abdomen tympanitic, considerable borborygmus. Pulse 65; heart sounds stronger, murmur still pronounced. Urine passed in twenty-four hours 1800 cc., specific gravity 1016, albumen not decreased; no change in condition of skin. Temperature: A. M. 98° F.; P. M. 98.8° F.

Treatment: Sponging and friction; same dietary with tr. ferri muriat. five c. c. t. i. d.

June 27th. Still extremely weak; voice stronger; mind easier; amnesic aphasia marked; appetite still morbid, always hungry; considerable flatulency; no stool. Aspect of skin somewhat improved in appearance, still dirty yellow (no spots). Temperature: A. M. 98.4° F.; P. M. 98.8° F.; pulse 66; respiration 14. Urine albuminous ($\frac{1}{12}$ tube), 1950 cc. in twenty-four hours, specific gravity 1018. Muscles beginning to fill out; very soft.

Treatment: Dietary increased to eight ounces broiled steak in morning; continued tr. ferri muriat.

June 28th. Gaining strength; dressed and sat up for a couple of hours, then felt exhausted and returned to bed. Mind quite tranquil; slept well; appetite still morbid; bowels moved; no change in character of stool; liver still inactive. Pulse 66, fairly good tone; anæmic murmur not so marked. Temperature: A. M. 98.2° F.; P. M. 98° F. Urine passed in twenty-four hours 1860 cc., specific gravity 1018; albumen present.

Treatment: Takes food at five stated intervals: six A. M., oatmeal, four ounces, broiled steak, eight ounces; ten A. M., Liebig's beef essence, one drachm in teacup of warm water; two P. M., one soft-boiled egg, with milk toast; six P. M., raw minced beef and onion; ten P. M., Liebig's essence of beef. Continue tr. ferri muriat., six c. c. t. i. d.

June 29th. Dressed and assisted to walk in ward-room a few steps. Muscles soft, very weak; limbs fill-

ing out; body weight, 129½ pounds (gain of nine and one half pounds for the week); pulse 68; urine 1650 cc. in twenty-four hours, albumen less; temperature, A. M. and P. M., normal; bowels moved naturally, stool still pitchy and offensive.

Treatment: Continue the same.

June 30th. Sleeps naturally, and awakes refreshed; allowed to read and talk; walks around for an hour or so with support; limbs filling out; feet œdematous toward night; appetite still morbid, unable to be satisfied with his allowance; good movement of bowels; albumen disappearing; heart sounds stronger; temperature normal. Continue restricted diet and iron.

July 1st. Felt quite refreshed on awaking; had slept well during the night; enjoyed morning meal, and ate without asking for more; as the sun was shining brightly, was assisted on deck, and sat in the air, well bundled up, for an hour; had but little appetite for midday meal. At four P. M. a small, dark, offensive stool; strained considerably, and was much exhausted afterward (nearly fainted). Administered spts. frumenti, half ounce, in aqua, at six P. M. Complained of severe pains in abdominal muscles and over the region of the liver (pains resembling hepatic colic); considerable febrile disturbance; pulse 98; temperature 100.2° F. Administered quin. sulp., at eight P. M.

July 2d. Feels much prostrated and weak; muscular pains and soreness over abdomen and back; complexion sallow; appetite poor; temperature: eight A. M. 98.8° F.; twelve M. 99° F.; four P. M. 99.2° F. Exhibited hydrang chlorid. mit., three cc., at eight A. M. Repeated dose at two P. M. Bowels moved three times; last evacuation watery; felt weak, but free of cramps; headache disappeared. Light diet of oatmeal and milk. Discontinued tr. ferri muriat.

July 3d. Still weak; muscular soreness over abdomen; no sharp pains; two loose evacuations from bowels; appetite returning; pulse 68; temperature normal; whiskey toddy, half ounce, t. i. d.

July 3d. Considerable improvement; pains have disappeared from muscles; tongue cleaner; complexion better; allowed to sit up to his meals; urine much improved, albumen ($\frac{1}{50}$ tube) specific gravity 1022; resume tr. ferri. muriat.; also vin. Portense ℥i. t. i. d. before meals.

July 4th. Gaining strength gradually; muscles soft; knees weak; encouraged to take some exercise daily, weather permitting, in the open air; digestion good; appetite under better control; liver still torpid; regular movement of bowels; skin clearing; lost clamminess; sleeps well; continue same. From this time forth gradual improvement; blood again examined microscopically shows marked diminution of white corpuscles. On July 8th no albumen found in urine. On July 12th anæmic murmer very indistinct. On July 17th arrived at St. John's; condition sufficiently to warrant his going ashore for exercise; muscles still weak and sore; filled out rapidly.

July 19th. Had a slight attack of intestinal indigestion; was living ashore at the consul's, and committed an error in diet; suffered for two days.

July 25th. Allowed to eat three full meals daily, with certain articles restricted; encouraged to exercise in open air. On the trip from St. John's to Portsmouth, N. H. (July 26th, August 1st), ran into damp moist weather; felt much prostrated, and muscles ached; given quin. sulp. 18 cc. every night during the passage. On being transferred at Portsmouth, his body weight was 169 pounds, representing a gain of 49 pounds in six weeks: 9½ pounds first week, 15 pounds second week, 8 pounds third week, 7 pounds fourth week, 5½ fifth week, 4 pounds sixth week.

Remarks: Vital depression as exhibited by the tempt. not marked; digestion fairly good all the time; nervous system soon calmed; microscopic examination of blood disappointing, exhibiting no unhealthy character of red blood globules; albumen disappearing; anæmic murmur disappearing, showing simply due to hydræmic condition of blood; liver not secreting; large gain in weight, due to rapid assimilation of food; owing to great muscular waste large urinary excretion (1950 cc. in one day), due doubtless to almost total inactivity of sudorific glands.

CAUSES OF DISCOLORATION IN GOLD FILLINGS IN TEETH.

BY WILLIAM HERBERT ROLLINS.

As pure gold is not supposed to discolor, the causes must be other substances which may be introduced in one or more of several ways: they may be present in or on the gold foil when received from the makers; they may be introduced by the operator in making the fillings; they may be present in the mouth itself.

The best way to begin the investigation was evidently to collect the discolored portions of fillings and analyze them. As yet no satisfactory result has been reached in this way, because the quantities were too minute.

The fillings themselves were next examined. Iron, silver, tin, and mercury were found. In which of the ways mentioned did these metals get into the fillings? The first attempts made to answer this question were to get samples of gold foil from the prominent makers, number them, and send them to Dr. Hills, of the Harvard Medical School, to be analyzed. The results of these analyses showed that none of the samples were pure. This was unexpected, as the makers guarantee their foils to be one thousand fine, or absolutely pure. Silver was found in every sample and iron in some. Extensive analyses made by the same chemist a year later showed the same results. The gold prepared by R. S. Williams always contained the least impurities. As the gold when received from the makers was always found impure, a short description of the manufacture may be of value as showing how impurities may be introduced.

The gold out of which foil is made is the mint gold, containing about two parts in a thousand of impurities. The makers dissolve this in aqua regia, filter, precipitate with ferrous sulphate, or more rarely with oxalic acid, wash the precipitate, melt it, and after casting roll to ribbons between steel cylinders. It is then beaten to the required thickness between pieces of glued skin, which are never clean.

Gold in this form I shall call plain foil, to distinguish it from the forms in use. Plain foil is not in the market. It must be obtained by special order. To get this plain foil into the numerous varieties required by those who fill teeth, it passes through several processes and then becomes soft gold, cohesive gold,

gold cylinders, gold blocks, gold pellets, etc., etc.; indeed one maker advertises over fifty varieties.

Cohesive Gold. Plain foil is heated (usually on an iron plate.)

Soft Gold. I am not sure how this is made, as makers of foil have their secrets, but as surface impurities have been found on this kind of foil it is probable that, in some cases, the softness is due to those impurities which prevent two surfaces of this gold from uniting, and thus produce the so-called softness.

Corrugated Foil. Alternate sheets of gold and thin paper are made into a pile, placed between two pieces of iron and heated in a furnace till the paper is consumed. The sheets of gold are then separated, the ash of the paper removed as much as possible, after which the leaves are placed in books, or used in the manufacture of gold blocks, gold cylinders, gold ribbons, etc., etc.

Gold Blocks, Gold Cylinders, etc. These are the forms of gold in most general use. To make them the foil (usually the corrugated kind) is subjected to various rolling, pressing, and cutting processes by iron machinery.

This brief description of the manner of making gold for dental use enables us to see how easily impurities may be present in the finished product.

Silver, which is always present in the gold before refining, is almost sure to be present after the process, through careless manipulation and poor acids. Iron is likely to be introduced from the ferrous sulphate, from the mould, from the steel rollers, from the plates on which the gold is heated, from the hands, from the machinery used to form it into pellets, cylinders, etc. Other impurities are almost certain to come from the skins used in beating, from the paper used in corrugating, and from the dust of the shop.

To test whether impurities could be introduced by a careful person in making fillings, the following experiments were tried. The foil used was plain foil, and contained no impurities except a small amount of silver, as shown by a very careful analysis by Dr. Hills: —

First experiment. The foil was prepared in the ordinary way, as follows: It was cut with steel scissors, heated on iron, handled with steel tweezers, condensed with serrated steel pluggers, burnished with a steel burnisher. Dr. Hills' analysis showed that iron was present in these fillings.

Second experiment. The same foil was treated as before, only iridium instruments, made by the American Iridium Company of Cincinnati, were used instead of steel. Iron was found in these fillings.

Third experiment. The same foil was cut with bamboo, handled with gold tweezers, heated on platinum and condensed with iridium points, and burnished with an agate burnisher. No iron was found in these fillings.

This brief description can give no idea of the amount of care and time which has been spent on these investigations. I give a short abstract from one of Dr. Hills' reports, but even this conveys no adequate idea of the amount of delicate works in the analyses: —

"It is proper that I should state that great pains have been taken in the analyses to arrive at correct results. In the beginning great difficulty was experienced in obtaining chemicals of the requisite purity, and it was only after considerable time and trouble that acids absolutely pure were secured. In order to make certain that, if any of the metals tested for were found, they were contained in the gold itself, blank analyses were made before each analysis of the gold, using the same apparatus and chemicals."

Thus far the only metals whose presence we have accounted for are iron and silver. The next question which arises is, How came the tin and mercury in the fillings in which they were found?

Almost every dentist now uses amalgam in greater or less quantity. This remains on the instruments in minute amounts, often invisible; and when, by accident or otherwise, the same burnishers perhaps are used in making a gold filling, a little of the amalgam gets upon the surface, showing itself after a time as a discolored filling. That this is a frequent cause of discoloration I have no doubt, and only by performing all amalgam operations in another room with an entirely separate set of instruments can we hope to get rid of the trouble. As an illustration, I should like to mention the following case: An amalgam filling had been made in the morning, the hands carefully washed, and other fillings of gold made before lunch. In the afternoon a large gold filling had been almost completed, but needed a little burnishing. The gold burnisher was moistened with soap and applied to the filling, which directly changed color. An examination of the burnisher showed the same trouble. For a long time I was unable to account for the mischief. At last it was traced to the soap, to which a little of the amalgam must have clung when the hands were washed in the morning after using the amalgam.

In the beginning of the paper three ways were suggested in which impurities might get into gold fillings. I have shown that in the first and second of these ways impurities are introduced, and with regard to the third way the following may be said: Certain medicines, as iron, when allowed to remain in contact with the teeth, cause a discoloration of the débris which collects about the fillings and on their surfaces. In the mouths of those who smoke, the deposits of epithelial cells mixed with lime and germs which collect about imperfectly cleaned fillings become darkened. This discoloration makes fillings in some cases almost black. Discolored fillings are due to many different causes, as I have shown. In conclusion, the following suggestions, if faithfully carried out, will do away with some of these causes: —

Demand purer gold from the makers. Use this in the form of plain foil, because this is least liable to contamination.

Never touch gold foil with steel instruments of any kind. If it is necessary to heat the gold, do this on platinum.

Keep a separate set of instruments for amalgam. Insist upon a thorough cleaning of the mouth every time food or medicines are taken.

RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M. D.

THE DESCENT OF THE TESTICLE AND THE NATURE OF THE GUBERNACULUM.[1]

THIS vexed question is ably discussed by Dr. Bramann, of Königsberg, who has studied it anew under the guidance of Professor Schwalbe. He begins with

[1] Archiv für Anatomie und Entwickelungsgeschichte, 1884, Heft 3, 4.

the inevitable historical introduction, which in this case is more interesting than it often is. Without mentioning the smaller points of difference, we may say that the gubernaculum testis is described by some as a hollow cylinder of peritonæum, but others hold that inside of the serous covering there is connective tissue or muscular fibre, or both. Seiler, Burdach, Müller, and Bischoff agree that it consists of a central cord of loose connective tissue extending upward from the scrotum, and continuous in part with the subcutaneous connective tissue. At its upper end it is attached to a jelly-like body. On the passage of the cord through the inguinal canal this connective tissue receives a covering of muscular fibres from the internal oblique and transversalis, which extend half-way up the gubernaculum. Outside of this the structure has a light layer of connective tissue from the fascia transversalis, and finally is covered by the peritonæum.

There is also much divergence as to the origin of the processus vaginalis: namely, the pouch of peritonæum lining the scrotum into which the testis descends. We may merely mention the old view, that it is formed by the pressure of the testis, as having, we believe, no modern supporters; but although it is agreed that the pouch is ready to receive the testis before the latter enters it, there is great uncertainty as to the period of its appearance. Some authorities claim that it is found in the four-month fœtus, others that it appears after the descent has begun.

Again, authors are not agreed as to the mechanism of the descent of the testis. One theory, and perhaps the most general one, is that the gubernaculum turns itself inside out like the finger of a glove; another, less clear, rests on the alleged opening out of the folds of peritonæum covering the gubernaculum, and according to the third the fibrous tissue of the gubernaculum shrinks. The theories just mentioned, excepting perhaps the last, that of the "shrinking," refer rather to concomitant changes than to the actual cause of the descent of the testis. Some hold that this cause is muscular traction, others the shrinking just mentioned, others the unequally rapid growth of different parts by which the position of the gland is necessarily changed, and others again the pressure of the growing abdominal organs. It is needless to say that we have mentioned only the leading tenets of the different parties in this controversy. To consider details would be well-nigh endless.

Dr. Bramann has investigated the matter by the dissection of more than forty fœtuses, and he has made both transverse and longitudinal microscopic sections of the gubernaculum.

Owing, apparently, to an unequal rate of growth of the walls of the body and the viscera, the testis descends toward the ring till the third month, when it again moves upward. It begins its final descent at the end of the sixth or beginning of the seventh month. The gubernaculum, when fully developed, arises at the external abdominal ring from the aponeurosis of the external oblique. It is joined by muscular fibres from the internal oblique and transversalis. In the main the description corresponds pretty nearly with that of Seiler and others, only the gelatinous body is wanting, the muscular fibres extend more than half-way up, and, originally at least, it does not arise from the scrotum. If it be pulled upon in an upward direction, the abdominal wall will follow, but the scrotum will not.

As the testis descends (the left one is the first to move), the gubernaculum appears to shorten, but this is deceptive, owing to the protrusion of the processus vaginalis into the scrotum. It is only when the testis has approached the internal ring that any real shortening occurs; till then the gubernaculum has simply moved bodily downward.

The processus vaginalis is to be seen as a small pouch of peritonæum as early as the third month, but it does not extend into the scrotum until the descent of the testicle begins. The gubernaculum lies in the posterior wall of the processus vaginalis, and as both descend, the former is turned inside out, its tissues passing over the latter so as to form the envelopes of the testis and vas deferens. This, however, applies only to that part of the gubernaculum below the point where it is pierced by the vas. From this it follows that the cremaster is formed from the muscular fibres of the gubernaculum.

As to the cause of the final descent Dr. Bramann has little positive to say. He denies that the shrinking of the gubernaculum pulls the testis downward, for in the first part of the process, as has been stated, the gubernaculum is not shortened, and later it is not fixed to the bottom of the scrotum. Still, our author admits that the shrinking of the central areolar part of the gubernaculum, which is continuous with the connective tissue of the scrotum, does play a part. He believes also in the influence of the pressure of the enlarging abdominal viscera. As a proof of this he cites the fact that when the sigmoid flexure is much distended with meconium, the left testis descends first. We are inclined to doubt, if not the principle, at least the illustration, on account of the uncertain position of the sigmoid flexure in fœtal life.

ON THE NATURE OF CERTAIN LIGAMENTS.[1]

Mr. J. B. Sutton has written a paper with the above title that is of much interest to those who consider anatomy from a scientific standpoint. He first treats of certain ligaments in the seal connecting the heads of corresponding ribs. These ligaments had already been described by Professor Mayer, of Bonn,[2] as *ligamenta conjugalia costarum*, and independently by Professor Cleland.[3] We will follow Mr. Sutton in reproducing the latter's description of these curious structures: "None of the ribs of the seal has the articular surface divided in two, but each of those that arise opposite intervertebral discs has a depression on the inferior margin of its articular surface similar to that on the head of the femur, and from this springs a strong and rather flat ligament, which, sheathed in synovial membrane, passes above the intervertebral disc, and is attached in the same way to the rib of the opposite side. It lies close to the disc which is grooved for it, and is covered by the superior common ligament. As it nears its attachment at each side it is flattened out, so as to lie like a fibro-cartilage between the rib and the intervertebral articular surface, and the head of the rib rolls on this structure. The synovial investment of the ligament and upper edge of the intervertebral disc are continuous with the joint on either side, so that there is one common synovial capsule in connection with the articulation of the heads of each pair of ribs to the

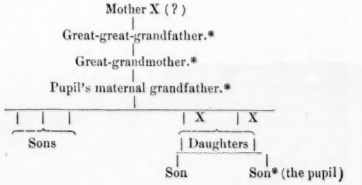
[1] Journal of Anatomy and Physiology, April, 1884.
[2] Müller's Archiv, 1834.
[3] Edinburgh New Philosophical Journal, 1859. Structure, Actions, and Morphological Relations of the Ligamentum Conjugale Costarum.

vertebræ."[1] This ligament has been found in many mammals, but apparently the synovial connection exists only in the seal. Mr. Sutton has discovered this band in the human fœtus from the seventh month till birth. Within a few months more it disappears, fusing with the disk in front, and contracting an intimate union with the posterior common ligament. The synovial connection is not found. Following Cleland, Mr. Sutton believes this to represent an important vertebral element, but he emphasizes the point that this ligament is represented by the transverse ligament of the atlas and by the odontoid ligaments, which seems very probable; but we cannot agree with him that "the singular condition of the ligament in the seal explains in a beautiful way the existence of a synovial cavity in so curious a situation as the back of the odontoid process." In the first place the situation is by no means a curious one, for it is elementary that synovial sacs occur where there is motion between two resisting bodies; and, secondly, we fail to see that the presence of these synovial sheaths in an aberrant type like the seal explains anything at all about the odontoid in other animals. If they were found in fœtal animals, the argument would be much stronger.

Mr. Sutton has made some interesting observations on the ligaments of the knee and foot. He finds that the internal lateral ligament of the knee-joint was originally a part of the adductor magnus, which in the four-months' fœtus runs to the head of the tibia. He holds also that the long external lateral ligament was originally the tendon of the peroneus longus, which in a fœtus a little older than the one just mentioned was found springing from the external condyle of the femur, and having but a very loose attachment to the head of the fibula. He finds a similar arrangement in the adult gibbon, and states that this muscle may often (in comparative anatomy) be found connected with the ligament.

"If a human fœtus, even as late as the sixth month of intra-uterine life, be examined by making a section vertically through the tendo Achillis, os calcis, and cuboid, it will be seen that ligament and tendon form one continuous band, and that the attachment of the tendon to the under surface of the os calcis is only of the loosest kind. After the seventh month of intra-uterine life the tendon becomes divided by extra growth occurring at the posterior extremity of the os calcis, the anterior portion becoming long and short plantar ligaments, the other gaining a permanent attachment to the lower border of the os calcis." The explanation of these changes is to be found, according to Mr. Sutton, in the stretching action the muscles undergo during growth, when the relative length of the segments of the limbs is changed.

VARIATIONS OF THE THORACIC DUCT.[2]



Mr. Arthur Thompson has examined the course of the duct in subjects in which there is no innominate artery, and the right subclavian is given off after the other branches and then runs across to its own side. In three cases which he has examined he finds that the duct opens on the right side of the neck instead of the left. In two of these cases the duct runs in front of the abnormal subclavian, and in one behind it. Little is known, unfortunately, of the early stages of the development of the thoracic duct, but we know that it not rarely is double for short distances, and that it is in close connection with the large arterial trunks; for these reasons Mr. Thompson believes that the explanation of the simultaneous occurrence of these anomalies is to be found in the history of the arterial development.

[1] Mr. Sutton does not appear to be aware that this ligament in the seal has been described also by Professor Lucæ under the name Ligamentum Capituli Costæ Intermedium. According to him the lateral parts are twisted instead of being flat. Robbe und Otter. Abhandl. Senckenberg. Natur. Gesel., Bd. viii., 1872.

[2] Journal of Anatomy and Physiology, July, 1884.

HEREDITARY DEFORMITY OF THE HAND.[1]

The following curious case of heredity, reported by Professor Turner, is remarkable for its completeness. One of his students showed the professor his left hand, of which the ring finger was more than an inch shorter than the middle finger. The phalanges were normal, the shortening being due to want of development of the metacarpal bone. We reproduce the family tree, as well as some of Professor Turner's remarks concerning it. The persons who presented the deformity are marked *. It is to remembered that "mother" at the top of the tree was the great-great-great-grandmother of the pupil.

"Thus my pupil's maternal great-great-grandfather had the deformity. He transmitted it to a daughter, and she to a son, who was my pupil's grandfather. There seems also to be a belief in the family that the great-great-grandfather's mother had the deformity.

"Again, my pupil's grandfather had three sons and two daughters. The sons were free, but the daughters had it. One of these daughters was my pupil's mother; he had a brother and sister who died in infancy, but does not know if their hands were deformed. Most likely they were not, or it would have been noticed. His mother's sister had a son in whom it did not occur. A peculiarity in the tree at once strikes one, namely, that the deformity has alternated from mother to son, and then again to the female line.

"Another peculiarity in the same family is a widening of the thumb and great toe, which sometimes occurs along with the short metacarpal bone, at others where the metacarpal bone is normal. My pupil has it, also his mother and her sister. One of his maternal uncles has it, and a daughter of that uncle, but they have not the short metacarpal."

[1] Journal of Anatomy and Physiology, July, 1884.

— One of the comic papers has this paragraph: "A patent medicine manufacturer died in New York last week. Before he died his friends asked him how he would like to be buried. He had just strength left to say: 'Insert me top column, next to reading matter, fifty-two times, electro by mail,' and then he closed his eyes, and passed away to that bourne where there are no omissions nor wrong insertions."

Reports of Societies.

REPORT OF THE EIGHTH ANNUAL MEETING OF THE AMERICAN DERMATOLOGICAL ASSOCIATION.

HELD AT HIGHLAND FALLS, NEW YORK, ON THE 27TH, 28TH, AND 29TH OF AUGUST, 1884.

First Day. Morning Session.

After the report of the Council of the Association and the transaction of routine business, the President, Dr. R. W. Taylor, of New York, delivered a brief introductory address, and then declared the meeting open for business, calling upon Dr. W. A. Hardaway to read the first paper on

A CASE OF XANTHOMA MULTIPLEX.

The patient was a man thirty years old, who had had the disease four years. Previous to its appearance his health had been good. The right half of his body, when first seen by Dr. Hardaway, was of a bronzed hue, the left yellow. The liver was much enlarged, thickened, and nodular, and there was a trace of sugar in the urine, the specific gravity of which was 1016. The body, the condition of which was minutely described, was almost covered with xanthomatous lesions in the form of tubercles, some as large as a pigeon's egg. Some could be felt deep in the subcutaneous fat tissue and also in the tendons. There were bony growths over the head of each tibia, and all the maleoli were enlarged to twice their natural size.

The lesions gave the patient but little trouble, his principal sufferings being due to his pulmonary emphysema, and to an intense pruritus which was general, and had annoyed him for a long time.

The author of the paper called especial attention to the fact that the bronzing of the skin antedated the xanthoma by some years, that the eruption was symmetrical except on the trunk, where it had assumed the form of an herpes zoster, and that internal organs were also affected. The bones were also involved, and he claimed that the peculiar distribution of the tubercles on the chest showed that the nervous system was probably influential in causing the disease.

DISCUSSION.

Dr. S. Sherwell said that he had never been able to establish a connection between xanthoma and hepatic disease. In all the cases he had seen the patients were otherwise healthy.

Dr. J. C. White remarked that it was very rare to find xanthoma associated with jaundice, he himself having noticed the connection only once in many cases that he had seen. He did not believe that the affection was of a diathetic nature. He had, however, seen several cases in one family.

Dr. L. A. Duhring called attention to the fact that the pruritus began with the jaundice and not with the xanthoma. He was inclined to believe that there was some connection between the formation of the tumors met with in this disease, and in those formed in some cases of urticaria pigmentosa. Under the latter term two distinct varieties of disease were often described.

Dr. Taylor agreed with the other speakers in denying the existence of a connection between xanthoma and a diathesis. He believed that if involution of the lesions ever occurred, it would be on the body, as he had never seen the disappearance of any lesions from the face.

Dr. Hardaway said that he had only the patient's statement to the effect that involution of some of the lesions had taken place. He thought the bone lesions of his case were extremely interesting and very rare. The connection between the two was very obscure.

First Day. Evening Session.

Dr. J. Nevins Hyde read a paper entitled

A CLINICAL STUDY OF LUPUS ERYTHEMATOSUS AS IT AFFECTS THE HAND.

The author described in detail the symptoms of the disease as exhibited by four patients under his care, three females and one male. In each the discoid variety of the affection was shown upon one hand, and of the four cases only one had facial lesions, which came out some years after the disease was fully developed on the hand. In several of the cases the fingers were involved, and in one the palm was extensively affected.

The paper terminated by a presentation of other cases recorded in literature of the same form of the affection. The prominent features in each case were tabulated, and from this comparison it appeared that the average age of the patients was somewhat over twenty years, and that about two thirds of them were women, thus confirming the observations made by Kaposi in 1882. The cases in which the hands were affected were all recorded by either American or English authors.

DISCUSSION.

Dr. White had seen three or four cases of lupus erythematosus in which the hands alone were affected. He had also seen cases of the disseminated form of the disease in which the hands were free. In none of them had he been able to recognize any evidences of a depraved condition of the system. He thought that cases in which the palms were involved were not extremely rare, but that the affection was often regarded as eczema or some other disease.

Dr. Sherwell had never seen the disease on the palms, but had seen it on the backs of the hands.

Dr. Taylor had seen two cases of the affection as described in the paper, one in a man, the other in a woman. Both were in good health and seemed free from diathetic taint.

Dr. Hyde stated that his main object in writing the paper was to point out the ease with which the affection could be recognized, and also to enrich the literature of the subject.

The second paper was read by Dr. S. Sherwell, and was entitled

A SUGGESTION CONCERNING THE TREATMENT OF ACNE AND ACNE ROSACEA IN THE MALE SUBJECT.

He said that too little attention had been paid to disturbances of the genital tract as causes of the diseases which formed the subject of his paper, and gave credit to Piffard and Hyde for having recognized their importance in this regard. He then spoke of the occurrence of chronic congestion and hyperæsthesia of the male urethra in some cases, and recommended for its relief the use of cold steel sounds. He concluded by detailing two cases which were greatly benefited by this means.

DISCUSSION.

Dr. A. R. Robinson thought the suggestion a sensible one, and that if followed benefit would result in some cases.

Dr. G. H. Fox spoke of the liability of physicians to ascribe results to a certain line of treatment, when the improvement might have been due to a change in regimen on the part of the patient without the knowledge of the physician. He also thought well of Dr. Sherwell's suggestion.

Dr. J. C. White next read a paper on

A CASE OF UNILATERAL CHROMIDROSIS (?).

It contained the report of a case of a workman in a sugar refinery, whose shirt had been stained a bright yellow color for several months. After wearing it a few days the left side all the way down seemed stained by saffron. There was apparently no excessive perspiration of that side of the body, nor were the garments stained elsewhere. An analysis of the material absorbed by the shirt showed that it was of an oily character, readily extracted by ether, and yielding peculiar absorption bands by the spectroscope. Its nature was not more definitely determined. It was also uncertain whether it was secreted by the sweat or by the sebaceous glands. The color was not due to the presence of bacteria, which have been found in some of the few cases of yellow sweat reported. The affection was immediately controlled by local treatment, and had not recurred four months later.

DISCUSSION.

Dr. Duhring thought that the description read gave an accurate notion of the disease, and he saw no reason to doubt that it was a case of genuine chromidrosis. He had recently seen a case of red sweat in a young woman, where it occurred in spots over the body.

Dr. Fox had never seen a genuine case of chromidrosis. He spoke of one which he thought genuine, but which was found to have been produced by the rubbing off on the chin and neck of the patient of the red dye from a bed-covering during the night.

Drs. Hardaway and Hyde had seen almost identical cases.

Dr. White explained that the query after the title of his paper referred to the uncertainty as to the source of the coloring matter.

Dr. White then read a paper on

CASES OF ARSENICAL DERMATITIS.

He gave brief notes of cases of supposed arsenical dermatitis in connection with the report of a train of uncommon cutaneous manifestations in a mother and her new-born child, after confinement within a chamber the walls of which were covered with arsenical pigments. The object of the paper was to raise the question, how far was the apparent case of "pityriasis maculata et circinata" in the mother dependent upon the presence of arsenical compounds in the atmosphere of the lying-in chamber, an affection concerning the ætiological relations of which nothing is known? In the infant the symptoms were of an eczematous type, with unusual manifestations of intertrigo.

DISCUSSION.

Dr. Hyde remarked that the number of artificial dermatoses was increasing rapidly, and that the question should always be raised in doubtful cases.

Dr. Sherwell said that the recital of the cases had made him think that a certain obscure case which he now had under observation might be an instance of arsenical dermatitis. The eruption was one of tense bullæ.

Dr. White said that the case might be one of poisoning from the bites of mosquitoes, acting upon a skin not accustomed to them. He had seen many cases where such an eruption was produced in this way.

The Association then adjourned.

SECOND DAY. MORNING SESSION.

Dr. L. A. Duhring read a paper on

DERMATITIS HERPETIFORMIS AND ITS RELATIONS TO IMPETIGO HERPETIFORMIS.

The paper, which in its first portion was practically a synopsis of one read at the last meeting of the American Medical Association, in its second part aimed to establish the identity of the disease with cases described by Hebra under the name "impetigo herpetiformis," which usually occurred in pregnant or puerperal women, and generally resulted fatally.

DISCUSSION.

Dr. Fox expressed the great satisfaction with which he had listened to the paper. He thought that great credit was due its author for taking so comprehensive a view of so many different forms of disease, which had been described under the names "pemphigus prurigi-nosus," "herpes chronicus," "herpes gestationis," etc. He now felt confident that they were all cases of the disease Dr. Duhring had so well described. He then reported a case of his own, which he had called chronic erythema multiforme pigmentosum, but which he now regarded as identical with the affection described in the paper.

Dr. H. G. Piffard said that the disease which had been so ably described was rare, and its manifestations not clearly marked. He felt sure that the affection was not closely allied to herpes, as its lesions were too polymorphous. He described at length a case of the disease which he had recently seen.

Dr. White expressed the great difficulty of classifying cases such as had been described. He was inclined to think that the term "multiform dermatitis" would better define the disease than that suggested by the author of the paper. He was not yet prepared to admit the identity of the disease with that of Hebra's cases, as he had never seen an instance of the latter. He also saw no valid reason for accepting the conclusion of the author that the affection was of a neurotic origin. He called attention to the fact that the disease was likely to be regarded as eczema by practitioners.

Dr. Hardaway thought that a certain number of cases with papular, vesicular, and pustular lesions could properly be called "herpetiform." He believed there was a neurotic basis to many such diseases.

Dr. Robinson spoke of three cases he had seen, and gave a careful description of one, of which he exhibited a colored drawing. He had recognized a neurotic element in the case, and had ordered the patient, a boy ten years old, to take nine drops of Fowler's solution three times a day. Speedy improvement followed.

Dr. Sherwell said that he believed that Hebra's cases were of a septic origin, and that they were in nature identical with the cases which are so common in hospitals infected with hospital gangrene.

DR. DUHRING said that his paper was based upon the careful study of sixteen or seventeen cases of the affection which had been under his care, some for a long time. He defended the use of the adjective "herpetiform" in connection with the disease, since in many of the cases the disease was from the first of a distinctly herpetic character. He reaffirmed his opinion that the difference between his cases and those of Hebra was simply one of degree.

The evening session was devoted to the presentation of the report of the Committee on Nomenclature, and the revision of the latter.

THIRD DAY. MORNING SESSION.

In the absence of their author, DR. HENRY W. STELWAGON, the secretary read two papers, one entitled

A CASE OF LATE CUTANEOUS SYPHILIS (ACNE-FORM SYPHILODERM OF THE NOSE), ILLUSTRATING THE OCCASIONAL NECESSITY OF LARGE DOSES OF POTASSIUM IODIDE.

The evidences of syphilis in the case were obscure, and the diagnosis was for a time uncertain. Only after the patient had for some time taken drachm doses of iodide of potassium three times a day did the disease yield.

The second paper was on

A CASE OF VITILIGO INVOLVING THE WHOLE SURFACE.

It described accurately the progress of the disease and the appearance of the patient.

DR. W. A. HARDAWAY next read a paper on

A CASE OF GENERAL IDIOPATHIC ATROPHY OF THE SKIN.

Photographs illustrating the case were exhibited.

The patient was a blind man, twenty-three years old. He had a sister also blind, and with the same skin disease, as he stated. The skin of his face was thickened and reddened, there were scars around his mouth, and he had the so-called "strumous lips." The integument of the trunk presented a checkered glistening aspect; patches of pigmented skin alternating with atrophic spots. The skin over the latter was tense and glistening, and could be picked up with difficulty. No dilated vessels were visible. The skin and muscles of the hand were atrophied, and the sides of the fingers had grown together over half their extent. There was necrosis of the conjunctivæ, corneal opacities and adhesion of the lids to the globes.

DISCUSSION.

DR. DUHRING said that the atrophy was the only essential feature of the disease under consideration. All grades are met with, from those having no tendency to degeneration to those developing carcinoma or sarcoma.

DR. TAYLOR said that in his opinion the condition of the skin in the case described in the paper was not like that met with in the disease known as angioma pigmentosum et atrophicum, as this patient presented simply an ill-nourished senile-like condition of the integument.

DR. WHITE was unable to agree with Dr. Duhring as to the affinity which he believed to exist between the different varieties of atrophic processes in the skin, which, in his opinion, varied widely. In one class we met with loss of pigment and a deposition of epithelium, without changes in the corium. In another hypertrophy of the corium was a prominent feature. In a third variety new growths were developed. He did not think the case reported could be associated with the last class.

DR. A. R. ROBINSON then read a paper on

MILIARIA AND SUDAMINA.

He first quoted the views held by different authors as to the true nature of a dew-drop-like eruption usually described under a variety of names, such as miliaria alba and rubra, sudamina, prickly heat, eczema solare, lichen tropicus, etc., and showed that they conflicted greatly. His object in preparing the paper was to attempt to accurately define the true nature of this eruption, and the conclusions he had reached were based upon original microscopical studies, drawings of some of which he exhibited.

He concluded that miliaria and rubra were simply forms of eczema, due to external irritation. He therefore thought that the term miliaria should be dropped.

The disease known as sudamina he had found to be not an inflammatory affection, but a disturbance of the sweat glands, the result of an hyperidrosis.

DISCUSSION.

DR. HARDAWAY was opposed to the use of the term eczematous as applied to the affection under consideration, which was a dermatitis, while eczema was a distinct affection.

DR. HYDE was inclined to fully accept the views of the author of the paper. He thought that miliaria and sudamina were solely due to accidents occurring in the course of eczema.

DR. WHITE agreed fully with the author of the paper, and recognized no such disease as miliaria alba and rubra. The question was after all one of definition only.

DR. DUHRING, while fully appreciating the value of the paper, thought that we should not lose sight of the clinical histories of the two affections. He was not yet prepared to look upon miliaria as simply a variety of eczema.

DR. R. W. TAYLOR then read a paper

ON A PECULIAR RINGED AFFECTION OF THE GLANS AND PREPUCE.

He described three cases of the affection seen during the past ten years. The patients were all men of middle age, and the disease was in all preceded or attended with neurotic disturbances. It appeared in the form of rings on the mucous membrane, and proved exceedingly obstinate, yielding only to large doses of arsenic. It showed no tendency to spread, and was not attended with hyperæmia. He was loath to regard the disease as one *sui generis*, but had carefully eliminated syphilis, ring-worm, and psoriasis in making a diagnosis.

DISCUSSION.

DR. DUHRING thought he had seen several cases of the disease. One or two of them he described at length. He had called them lupus erythematosus, to the gross appearances of which disease they bore a marked resemblance, and he was inclined to regard Dr. Taylor's cases as instances of that affection.

DR. WHITE had had one case under observation for

some time. He had made no positive diagnosis, and the patient had not improved.

DR. HARDAWAY described a similar case occurring in a man who had had psoriasis. The lesion on the glans was, however, not psoriasis.

DR. ALEXANDER suggested that the disease might be analogous to leukoplakia buccalis.

DR. WIGGLESWORTH cited the case of a man under his care who had had leukoplakia, and who afterward developed a lesion on his penis resembling that described by Dr. Taylor. It ultimately disappeared under the use of pure carbolic acid.

DR. TAYLOR was positive that his cases were not instances of lupus erythematosus, but were totally unlike that affection.

OFFICERS FOR 1884–85.

President, Dr. W. A. Hardaway, of St. Louis.

Vice-Presidents, Dr. J. C. Graham, of Toronto; Dr. A. Van Harlingen, of Philadelphia.

Treasurer, Dr. George H. Rohé, of Baltimore.

Secretary, Dr. W. T. Alexander, of New York.

Mr. Jonathan Hutchinson, of London, Eng., was elected to honorary membership.

The following gentlemen were chosen as active members: —

Dr. George H. Tilden, of Boston; Dr. A. R. Morison, of Baltimore; Dr. F. C. Curtis, of Albany; Dr. L. N. Denslow, of Minneapolis.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 4, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

THE DIAGNOSTIC USE OF QUESTIONS.

THE judicious use of questioning as an aid to diagnosis is an accomplishment not always easy for the physician to acquire. In proportion as a man's habits of thought are orderly and logical, to that degree will it be his aim to secure precise and definite information regarding every symptom of disease in a given case that presents itself. Physical exploration by the many "scopes" that medical science has invented in the last few decades is taught with great care in our best schools. But the art of gaining knowledge of those phases of disease which have transpired before the patient comes under the professional eye, or of those symptoms which, being purely subjective, can be learned only by the patient's word, is often, perhaps, not given sufficient importance in courses of medical training. To be sure, a clinical lecture is, or should be, an exemplification of the best method of this most delicate of all species of exploration, but it can hardly take the place of personal practice therein by the student himself under the constant suggestion and comment of the instructor. Much judgment is needed as to how far to make use of leading questions. Undoubtedly under certain circumstances they are of use as suggesting to the patient points which he would otherwise have forgotten, or would have thought unworthy of mention, and which yet have an essential bearing upon the case. For it is often the "unconsidered trifles" which are of value to the diagnostician. But, on the other hand, the hysterically inclined will "take suggestion as a cat laps milk," and every new symptom learned of is promptly added to the catalogue of woes. Probably many a physician has now and then yielded to a sudden temptation when talking with such a patient to ask some such question as "Have n't you sometimes had a stinging sensation in your left ear?" sure of receiving at least a qualified affirmative.

One great obstacle stands in the way of reducing diagnostic questioning to a fine art, and that is in the patient himself. It cannot be denied that upon the average intelligence subtle distinctions in the phraseology of questions, discriminating endeavors after the logical order of subjective symptoms, are often largely wasted. Good workmanship will fail if the material used is poor, and, unfortunately, many minds are of such poor stuff as to make it almost a waste of time to attempt to extract from them carefully considered statements. We can get at facts only through the media of ignorant or confused intellects. The sources of error are numerous and glaring. The original sensation may not have been correctly transmitted to the patient's cerebrum; it may not have been correctly perceived; the original perception may have been forgotten; the power of reproducing, formulating, and describing the sensation may be impaired or absent. Occasionally there is aversion to talking at all or to telling the truth. Patients think they are being badgered. We remember hearing an eminent clinical teacher, now deceased, ask a patient, before a class, regarding the possible hereditary nature of his disease. The colloquy was somewhat as follows: —

"What did your father die of?"

"Don't know."

"Did he ever have shortness of breath?"

"Think he did."

"When?"

"Just before he died."

"Do you know whether he had consumption?"

"No, I don't."

Several more questions were asked with no success in elucidating the point of heredity. Finally, in despair, the professor said, —

"How old was your father when he died?"

"One hundred and two."

We know how badly even honest and competent witnesses often fare when under cross-examination. The physician cannot expect the average patient, however well disposed, always to tell a perfectly straight and coherent story. An intelligent and truthful man will vary his narrative of the same facts from time to time according to the shading of the questions or the

order in which they are asked. It remains for the practitioner to frame his inquiries as simply and directly as possible, and, especially before those in weakness and suffering, to avoid anything suggesting the methods of the cross-examining criminal lawyer.

PRESENT DOCTRINE AS TO MEMORY-LOCALIZATIONS.

On a recent visit to a watering place we had the pleasure of listening to the performance of an aged vocalist — now in his ninety-first year — who has been totally deaf for thirty years. Despite the fact of deafness, the singing was in every way correct, the essentials as to *length*, *pitch*, and *power* being observed. The old gentleman was also able to play accurately on the violin many tunes with which he had in former years been very familiar.

Physiology is now able to give a sufficiently satisfactory explanation of phenomena of this kind which seem so mysterious to people in general. It is pretty generally agreed that the substrata of motor-memories — concerned in the movements of vocalization and musical expression — are situated in certain definite cortical areas in the anterior and parietal regions of the hemispheres. The principal centre is undoubtedly Broca's speech convolution in the left frontal lobe, but the centres of facial expression in both hemispheres have a part.

In instrumental performances the cineritious zones in the parietal lobes, known as Ferrier's Centres, are brought into exercise, while visual and auditory memories are located, the one set, according to Munk, whose experiments are very decisive, in the occipital region, the other in the upper temporo-sphenoidal lobe. (Ferrier, Munk, etc.) In the cerebrum of our aged musical friend, who did not appear to have lost his hearing from any cortical lesion, all the above-mentioned centres were presumably intact, and ready to respond to incitations; and all that was needed was the proper stimulus to set in motion a quasi-automatic machinery in whose direction the exercise of audition, though a helpful is by no means an indispensable factor.

Munk, who assigns to the memory of sight-perceptions an indefinite region, inclusive of Ferrier's visual centre, in the occipital and the posterior parietal lobes, has made a number of very interesting experiments in dogs, which throw a wonderful light on the functions of this part of the cerebrum. These experiments have been very graphically described by a recent writer in the *Popular Science Monthly*:[1] "In the first dog the entire posterior part of the brain was removed, and the dog was made permanently blind. In the second dog a portion of this part of the brain was cut out and the dog was deprived of his sight-memory. He was, however, able to recover. Successive operations repeated on the same dog showed that recovery was always possible until the entire posterior part of the brain was removed, when, like the first dog, he became permanently blind. The recovery then was possible because around the area cut out there was left a ring of gray matter which was in connection with the eye, and in this ring of gray matter, which formerly contained no memory-pictures, the new memory-pictures were stored. All the posterior part of the brain in the dog is therefore a *potential* area for sight-memories. The *actual* area for sight-memories occupies only a part of this potential area. If the actual area be cut out, a part of the potential area still remains; the dog is temporarily deprived of sight-memory, but can recover it. If the potential area is entirely extirpated, the dog remains blind and can never regain its memories. This distinction between actual and potential memory is borne out by similar phenomena in man."

These observations are in striking correspondence with the discovery of Huguenin, establishing direct anatomical relationship between the optic nerves and the occipital lobes. In one case of unilateral blindness of several years' standing, he found atrophy of both occipital lobes, much more marked, however, in the side opposite to the affected eye (the right side). This was accompanied by pronounced atrophy of the left optic nerve.

In another case, blindness of both eyes, existing from infancy, was found to coexist with atrophy of both occipital lobes.[2] Monakow always succeeded in "obtaining atrophy of the primary visual centres in rabbits after removal of a very limited portion in the occipital region, a part corresponding to the area in the dog which Munk has termed the visual area."[3] Other observations by Monakow, Gudden, and Ganser[4] render such anatomical relationship well-nigh proven.

With regard to the auditory centre, — centre of hearing, perceptions, and memories, — Ferrier, Munk, and Luciani agree in locating this centre in the superior temporo-sphenoidal convolution, destruction of this area, on both sides, in dogs, being attended with complete failure to respond to ordinary auditory stimuli, — in other words, being accompanied with deafness. Munk's experiments go to show that there is an *actual* and a *potential* area in this centre, just as in the case of the visual zone. If the actual area be extirpated, "the animal loses all memory of words and commands formerly recognized, attaches no meaning to the cry of its puppies, to the snap of the whip, or to its master's whistle." This *word-deafness* may, however, be recovered from in the dog, a gradual process of education developing new auditory residua in the potential area. If, however, the latter be extirpated, the animal becomes totally and permanently deaf.

An interesting case of *word-deafness* (with aphasia) confirmatory of the now generally admitted auditory localizations has been lately communicated to the Biological Society of Paris by M. Magnan.[5] The subject of the report died of cerebral *ramollissement*, had long been aphasic, and deaf to all comprehension of words, though understanding perfectly the language of signs.

[5] Journal de Thérapeutique, June 10, 1883, p. 435.

He even took pleasure in the reading of journals, and retained his ability to write. In other words, he had lost the faculty of perceiving *sound* images, while still keeping in its integrity the notion of written images. The autopsy of this patient disclosed diffuse sclerosis of the third left frontal convolution, with extensive softening of the temporo-sphenoidal lobe, "the maximum of intensity corresponding exactly with the region which has been pointed out as the perceptive seat of hearing." M. Magnan relates the history of another case very similar, except that here it was the angular gyrus which, along with the third frontal, was the focus of *ramollissement*. The patient, besides being aphasic, had lost all perception and memory of visual or written images, while recognizing and responding to sound images. These observations, which were made with great care, lend powerful support to the localization doctrines now so generally held. M. Magnan observes that we have here "a new proof of the existence of distinct perceptive centres for the different sensorial organs." It is also a striking fact, he remarks, that certain aphasics affected with *word* blindness learn to read raised letters like ordinary blind persons. This fact demonstrates that the encephalic perceptive centre where the retinal impression is recorded differs from that of touch and of the muscular sense; but where the one avenue of sensation is obstructed, the impression may be conveyed by some other more pervious channel to the centre of ideation." Ferrier concludes from numerous experiments that the seat of tactile memories is in the hippocampus, and he asserts that he has destroyed almost the whole outer surface of the hemispheres without causing loss of the sense of touch.[1] Later experimenters have, with strong probability, assigned almost the whole of the parietal motor region to tactile perception, the small cells of the deeper strata being concerned in this function.

It is evident that we are still on the threshold of this interesting inquiry. Certain facts are looming up with tolerable clearness: that the old phrenology is utterly erroneous; that important regions on the surface of the hemispheres, formerly assigned to psychical functions, are devoted to motor and sensory residua, — the memory of impressions and motor combinations, — and that *character* is dependent on other conditions than prominences of gray matter; that every centre of perception or muscular movement is also the centre of the particular memories connected with such movements or perceptions; and that our memories of speech, our visual memories, our auditory memories, our memories of motion may each be lost while other memories remain intact. All this has been as good as demonstrated within the past fifteen years.

MEDICAL NOTES.

— The use of undiluted cows' milk for infant-feeding received further advocacy in a lecture recently delivered at the Health Exhibition by Mr. Edmund Owen, F. R. C. S., on the rearing of hand-fed infants, the chair having been taken on the occasion by Dr. Charles West. Mr. Owen contended in favor of pure fresh milk as the best staple food of young infants during the first six months of life; and speaking of condensed milk, he declared himself unable to comprehend how any superiority could be claimed for condensed milk, this having been evaporated almost to dryness, mixed with sugar to prevent its going bad, soldered down in tin pots, and stored for an indefinite time in an oil and color shop. Insistence was also placed on the employment of the old-fashioned feeding-bottle, by using which all tubing was dispensed with, and regularity in feeding insured, since the bottle must be held by the nurse during the whole time the child sucked from it. The lecture is an interesting contribution to the literature of the subject it discusses; its facts and advice stated plainly and in a way to be understood by those chiefly concerned; and its delivery in connection with the great exhibition at South Kensington will no doubt be productive of good results.

— The Signal Service of the United States has taken measures to notify of the approach of marked changes in temperature by a system of signals. The "cold-wave flag," white with black centre, will be displayed at the central station, and it is suggested by the chief signal officer that smaller flags (to be procured by individual contributions, as the department has no money available for such uses) be shown at all places to which the *Farmer's Bulletin* is now supplied. The advantage of a general warning of approaching thermometric changes to many industries and interests is obvious.

— Noble Smith enters a protest, in an article on Postures in School, their Influence upon Physical Development (*Medical Times and Gazette*, August 9, 1884), against checking the natural activity of childhood. He considers that "the formation of the skeleton favors the production of deformity when constrained postures are maintained for long periods," and instances the effect of posture upon adults in the different trades: the waiter in restaurants becomes flat-footed and knock-kneed; the seamstress, the clerk, and the engraver show by their rounded backs the effect of long-continued posture. He writes that "it is a false system to attempt to refine young girls by restraining their natural freedom of movement. It is this false process which does so much to encourage the production of deformity. Long walks in precise and stately file produce a harmful strain upon the spine and legs, whereas free movement in such games as cricket and lawn tennis affords a healthful exercise." Touching upon the cause of the greater frequency of lateral curvature in girls, he thinks that all the factors in the formation of curvatures of the spine occur to a greater extent in girls than boys, in that "from infancy upward girls are discouraged from playing and romping."

— A remarkable case of hasty diagnosis and, it is to be hoped, an equally remarkable one of mulish obstinacy on the part of the mistaken practitioner, was brought to trial, early in August, at the Hants Assizes, in

[1] Functions of the Brain, p. 177.

England, before the lord chief justice. It appears that the plaintiff, Mr. Yarndley, whilst on yeomanry duty, in June last, became saddle-sore, a circumstance by no means uncommon to persons not in the habit of riding much. In order to protect the abraded skin he applied a handkerchief to the part. On his return home his wife, not being satisfied in her mind as to the origin of the blood stains, took the kerchief to a local practitioner (Dr. Pike), who pronounced in favor of the husband's misconduct. Nor did he retract his expressed opinion after he had personally examined the plaintiff at the invitation of the latter. Horrified at the charge made against him, Mr. Yarndley sought the advice of several doctors in the neighborhood, who unanimously declared that the diagnosis made by Dr. Pike was incorrect, and, with true professional courtesy, advised him to withdraw it. For some reason or other Dr. Pike failed to do this. Hence the action brought by the plaintiff to clear his character from the aspersions cast upon it. Apart from the fact that no manner of stain upon clothing could in itself be taken as proof of venereal disease, the circumstances were strongly suggestive of what was, no doubt, the real explanation, for the wound on the thigh exactly corresponded with the blood-marks on the trousers.

— Dr. M. G. Biggs reports this case in the *British Medical Journal*, May 10, 1884: "E. S., aged sixteen, a servant, had never menstruated, although she was a well-formed girl. She had, however, suffered from pain at distinct intervals, and, when she sent for me, her mother said she had been in severe pain all the previous night, and was then so bad that she was rolling on the bed, and that the womb had come down externally. On examination there was a distinct bluish projecting membrane, with marked fluctuation; the only opening to be found was that of the urethra. A triangular piece was removed from the centre of the membrane, and there was an immediate rush of a considerable quantity of dark-colored discharge, with instant relief from the pain, which did not recur. When the discharge had ceased the parts were covered with a piece of linen rag soaked in carbolic-acid lotion (one in forty), and this was ordered to be continued; but, as often happens in this class, the mother was somewhat careless, the rag was allowed to dry or to fall off, so that we may fairly say that there was a free access of non-carbolized air. She was kept in bed during the remainder of that day and the next, but there was no rise of temperature, and then she was allowed to get up and resume her work, which she did without any bad effects."

— A case is reported in the *Medical Times and Gazette* (April, 1884) of a primipara who was delivered on May 20, 1873, of an unusually fine male child, but having a large spina bifida of all the lumbar and one or two of the lower dorsal vertebræ, the integuments of which were so thin and transparent that the vertebral canal was distinctly visible with its contents. The child was dressed with the usual abdominal bandage, the pressure of which caused suppurative inflammation and thickening of the surface of the tumor, so that by August of the same year nothing remained but a fleshy mass, pressure on which caused no discomfort. About this time, however, the head was noticed to be becoming larger. By Christmas it was very large and cumbrous, and on the evening of January 24, 1874, it burst, and seven and three-quarter pints of slightly bloody serous fluid were collected in a pail. The child seemed relieved by the discharge, and slept better than usual, but died seventeen hours afterward.

— A case of poisoning resulting in one death is reported from Philadelphia. The accident seems to have been due to a misapprehension that certain small pills were homœopathic, whereas they actually contained one twentieth grain each of strychnia. A party of five were seated at the supper table, when, just previous to eating, one of the party produced a box containing about fifty granules, the directions written upon the box being to take one before each meal. The others at the table passed the box around, each taking some. One took nine, the others emptied the box, each taking probably at least five. One female swallowed a quantity not exactly known, but probably amounting to at least half a grain. She died in about three hours, after protracted tetanic convulsions. All the others were also affected in the same manner, with cramps and painful contractions of muscles; but, under medical treatment, they recovered after several hours' suffering.

Correspondence.

ANTHROPOPHAGY.

MR. EDITOR, — In an article on Anthropophagy, in connection with the Greely party, which appears in your issue of the 21st inst., I am glad to see expressions of pity for the unfortunate men who were reduced to such a direful extremity, and indignation against those who are to blame for leaving them to suffer and to die on the inhospitable shores of the Arctic Ocean.

We, as physicians, have nothing to do with the moral question involved; but as you discuss the subject of human flesh as food, I would call your attention to the case of the wreck of the schooner Almon Bird, published in full in the *Boston Sunday Globe*, January 8, 1882. Briefly stated the facts are as follows: She foundered in a gale January 2, 1882, and the crew, or the survivors of them, were picked up some forty miles north of this (Cape Ann) and brought in here by one of our fishing vessels. The men were exposed for three days and nights in an open boat. All were wet through but the mate, and he was the only one who escaped frost-bite. Three men died in the boat, and one a few days after being rescued, his feet and legs frozen stiff almost to the knees, all his fingers and both thumbs also. The captain's feet were badly frozen and he lost portions of both of them.

On the morning of the third day, says the captain, "famished with hunger and actually dying with thirst, we were compelled to do that which made our hearts revolt with horror. Driven to the last resort, and in an untold agony of desperation, I opened the jugular vein of the second mate, who had been dead about two hours, and we wet our parched lips and throats with his blood, still warm. . . . The draught of blood re-

vived us wonderfully, and it is my earnest belief that it was that alone which saved our lives."

I happened to be one of the physicians who had charge of these men after they were landed, and they all assured us that it did "*revive them wonderfully.*" "It put new life in me," was the way each one expressed himself. Of course we felt delicate about questioning them much, and consequently did not make very particular inquiry, but every one here knew it, and no one thought for one moment of blaming the poor fellows, as each heart was filled with pity for the unfortunate men. These men had some food (pilot bread) but no water.

Thinking these facts might be at least interesting, if not valuable, has induced me to send them to you to do as you please with them. Yours very truly,

AUG. M. TUPPER, M. D.

ROCKPORT, *August* 25, 1884.

OBITUARY: THE LATE SURGEON JOSEPH JANVIER WOODWARD.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C., *August* 20, 1884.

IN announcing to the officers of the Medical Department the death of Joseph Janvier Woodward, Surgeon and Brevet Lieutenant-Colonel, United States Army, which occurred near Philadelphia, Penn., August 17, 1884, the Surgeon-General wishes to offer his tribute of respect to the memory of the deceased, whose distinguished career and valuable services, for a period of twenty-three years, have shed lustre on the corps, and for whose untimely loss feelings of profound regret will be shared alike by his comrades in arms and by the profession at large.

Dr. Woodward was born in Philadelphia, Penn., October 30, 1833, and was educated at the Central High School of that city, graduating with honor as Bachelor of Arts in 1850, and receiving the degree of Master of Arts from the same institution in 1855.

He graduated in medicine at the University of Pennsylvania, April, 1853; entered the army as assistant surgeon August 5, 1861; became captain and assistant surgeon, July 28, 1866; major and surgeon, June 26, 1876. "For faithful and meritorious services during the war" he received the brevets of captain, major, and lieutenant-colonel, United States Army.

He was assigned to duty in this office May 19, 1862, and from that date until the beginning of the illness which terminated in his death was intimately identified with its professional and scientific work.

While the valuable results of his life's labor are comprehended in a long list of miscellaneous publications, both professional and scientific, too familiar to the corps to require individual mention, his greatest triumphs were won in the field of microscopical investigation, in normal and pathological histology, and in his happy application of photo-micrography to the purposes of science. In these pursuits he attained remarkable success, and achieved an enviable, world-wide reputation, leaving to science and medicine lessons of undoubted value and usefulness. Of his strictly professional work the medical portion of the Medical and Surgical History of the War of the Rebellion was the crowning achievement. In the second part of this work he developed the results of his careful investigations into the nature and pathology of the intestinal diseases which had proved so fatal in the late war. Here also he displayed his wonderful capacity for that minute and exhaustive research which forms so striking a feature of his writings.

As in the case of his co-laborer, Otis, he yields to other hands the honor of completing his labors.

In addition to his engrossing professional duties, his restless activity of mind led him to seek recreation in his favorite studies, physics, art, and philosophy.

Endowed with a retentive memory and of untiring industry, he acquired a vast store of information which he held available for use at will; fluent of speech, he took delight in the expression of his views and opinions both in social converse and in the arena of scientific debate.

His fund of knowledge, his strong convictions, his tenacity of opinion, and his quick perception, made him a controversialist of no low order.

With such a record it is needless to speak of his zeal, his ambition, or his devotion to his profession, and especially to the reputation of the corps of which he was so bright an ornament.

Of a sensitive, highly-strung, nervous organization, the confinement, anxiety, and labor to which he was subjected in his attendance upon the late President Garfield during his long illness proved too much for a mind and body already overstrained by incessant labor, and precipitated the illness which finally terminated his life.

At the time of his death Dr. Woodward was a member and ex-president of the American Medical Association, a member and ex-president of the Washington Philosophical Society, a member of the National Academy of Science, of the Association for the Advancement of Science, of the Academy of Natural Sciences of Philadelphia, and of the College of Physicians and Surgeons of Philadelphia. He was an honorary member of several American and foreign scientific, medical, and microscopical societies, and the recipient of many distinguished honors from learned bodies in this country and abroad.

R. MURRAY,
Surgeon-General United States Army.

Miscellany.

INTERNATIONAL COLLECTIVE INVESTIGATION.

THE address of Sir William Gull before the International Medical Congress at Copenhagen, in which he strongly urges the adoption by the universal medical world of that system of collective investigation of disease which the British Medical Association has been employing with such satisfactory results both in present attainment and in anticipation, has been published in full in our English contemporaries, and is a strong plea. The *Medical Times*, commenting upon it, points out that this method of investigation is not a modern project, but that it suggested itself to Lord Bacon three centuries ago as the *novum organon*, — the "new machine" whereby the facts of nature might be observed, arranged, and treated in such a way as to come within the mastery of man.

As medicine is to be the first science to which this new modification of the Baconian method is to be applied, remarks the *Times*, so, it may be pointed out, it is almost the only one in which it would be practicable.

In no other branch of natural science are there so many observers more or less efficiently trained, and enjoying, from the very nature of their daily work, so many hourly opportunities of registering important facts. Even as it is, medicine, like botany and zoölogy, has been in great measure built up of facts observed by, so to speak, amateur observers, that is, observers with whom observation has been the secondary and not the primary business of their lives. The only matter for surprise and regret is that the valuable work of these observers has not already long ago been systematized, directed, and stimulated by some central organization. Hereafter, let us hope, the present generation and the present year will be looked back upon as forming as important an era in the progress of medicine as the publication of Bacon's great work formed in the history of scientific inquiry in general. After the forcible and closely reasoned address of Sir William Gull, we do not think that there will be many who will have the courage to augh down the new movement. Difficulties of course there will be. The average man is not to be turned into a trustworthy observer, because his observations are collected and published. The "idola" of which Bacon warned us will still distract and disturb the search after truth; but, as Sir William Gull has shown, the very magnitude of the operations of the Collective Investigation Committee will tend to neutralize and eliminate these sources of error. The "idola tribûs," the errors to which minds are liable from their national constitution, will be naturally reduced when many nations share in the work; while the "idola specûs," the errors arising from egoism and individual bias, will be eliminated when the observer is only an impersonal unit in a vast multitude of fellow-workers. It may be calculated that those who only work for personal renown will not enter enthusiastically into the movement, but that it will be left to such as are actuated mainly by love of truth and an ardent desire for human welfare, — the motives which the author of the "Novum Organon" put forward as the main incentives to scientific research.

THE HYPODERMIC INJECTION OF AMYL AND EPILEPTIFORM CONVULSIONS.

DR. SYDNEY RINGER, according to the *London Medical Record* (August 15th), has noticed the occasional action of the nitrite of amyl upon the heart, and the strange effect sometimes produced upon the nervous centres. He says: "I have seen one case where a woman immediately after a drop dose turned deadly pale, felt very giddy, and then became partially unconscious, remaining so for ten minutes." And again: "A delicate woman, after one-thirtieth of a drop, passed in a few moments into a trance-like state." In a case described by Dr. Strahan,[1] a chronic maniac, aged fifty-three, had suffered for several days from severe lumbago; a ten-minim dose of a ten per cent. solution of nitrite of amyl in rectified spirits was injected hypodermically. "Immediately after the injection the pain disappeared. He got up from the bed, and at my request stooped and touched the floor with his fingers. In, as nearly as could be guessed, about a minute and a half, he suddenly became deadly pale, and sank back upon the bed." Then his face, head (bald), and neck became congested, and he was strongly convulsed for about half a minute. The convulsion affected the face and arms strongly, the legs slightly. The teeth were ground, and the breathing was suspended. In a few minutes, after coming out of this fit, he was attacked by a second one, during which the heart's action became very faint. He was made to inhale some chloroform, and the fits did not return. The lumbago entirely disappeared. This observation is interesting, as inhalations of nitrite of amyl have been recommended, both in England and in Italy, to check the recurrence of epileptic convulsions.

THE DEATH CERTIFICATE IN A CASE OF SUICIDE, WITH REFERENCE TO INSURANCE.

THE president of the Medico-Chirurgical Society of Edinburgh recently exhibited before the Society[1] the parts from a case of cut-throat, with remarks bearing on the liability of life insurance companies. The cut happened in the person of a constable who had been troubled for about six months with insomnia. One morning he got up about four, after a restless night. His wife, who was sleeping in another apartment, heard a heavy fall and a deep moan, and going in found her husband lying on the floor, and blood flowing from the neck. Strange to say he was able to articulate, and said he had cut his throat. His larynx was opened into, the epiglottis cut across. No important vessel was wounded, but there must have been considerable hæmorrhage. He was taken to the infirmary, but died on the way. The body was taken home after two days, when the widow consented to have a post mortem performed, the reason for this being that the man was insured, and he (Dr. Littlejohn) was of opinion that if an autopsy revealed cerebral disease the medical attendant was entitled to give such a certificate of death as would cause even those insurance companies who forfeited the policies of suicides to pay the policy. In this instance he was glad to say he found traces of chronic cerebral disease, great adhesions of dura mater to bone, adhesions in arachnoid cavity, a large amount of sub-arachnoid fluid, and roughness of the internal surface of the cranium, justifying him in giving a certificate of chronic cerebral disease, with a wound in the neck, which was available in procuring the insurance money.

THE PATHOLOGY OF OBESITY.

PROFESSOR KISCH, of Prague, has recently contributed to the *Deutsche Medizinal Zeitung* an article on the above subject, in which he considers the derangements, functional and organic, to which the corpulent are specially predisposed. The *Medical Record* (August 16th) in its editorial columns thus enumerates some of these conditions: —

"First, as regards the heart, an organ which is inclined early to show signs of disturbed action. The fatty heart, as distinguished from the fattily degenerated heart, is affected, according to Leyden, in three degrees of severity. In the first there is simply a thick layer of adipose about the organ; in the second, with the fatty deposit there is a softening or relaxation of the muscles, dilatation of the cavities, and enfeeblement of action. In the third form there is combined

with the fatty heart an arterial sclerosis. The symptoms in the higher grades of fatty heart resemble considerably those of fatty degeneration, and need not be here enumerated. Kisch has made sphygmographic tracings in four hundred cases of fatty heart with the following result: In thirty-six per cent. of cases there was a *pulsus tardus;* in thirty-two per cent. of cases the pulse varied from one of a slightly to one of a completely dicrotic character; in twenty-four per cent. of cases an increase of tension from arterial sclerosis was shown; in four per cent. of cases there was simple arythmia. The value of these examinations is, of course, slight of themselves. It is to be assumed, though it is not stated, that the patients had no valvular disease of the heart and no kidney lesions.

"As regards the respiratory organs, Kisch found in many cases bronchial catarrhs. Naturally such symptoms as dyspnœa, and even pseudo-angina, were frequent.

"The digestive organs of the obese are very likely to be deranged. Gastro-intestinal catarrh, dyspepsia, constipation, hemorrhoids are present, and are due partly to dietetic errors, partly to the weakness of the heart and the incapacity or disinclination on the part of the patient to take sufficient exercise. An enlarged and fatty liver is of frequent occurrence, but its existence is not easy to make out by physical examination.

"Urates, uric acid, and oxalate of lime are found in the urine. It is well known also that the obese are liable to glycosuria, and Kisch found sugar in the urine of many of his patients at periodic or irregular intervals.

"Owing to the increased activity both of the sweat and the sebaceous glands, fat persons are subject to 'catching cold' and to attacks of rheumatism. Such skin diseases as boils and carbuncles are relatively frequent.

"The bodily temperature shows an inclination to mount up, and in fevers the corpulent burn actively. Their feebler resistance to fevers was first pointed out by Hippocrates. Liebermeister states that they are less amenable to antipyretic measures.

"Parallel with increase of fat is a decrease of sexual appetite and sexual power. Kisch found in several cases absolute azoospermia. Women are inclined to amenorrhœa and sterility. Among two hundred and fifteen obese women Kisch found forty-nine cases of amenorrhœa, one hundred and nineteen of scanty menstruation, and forty-nine of sterility.

"The blood of the obese is poor in red blood-corpuscles. Obesity is, in fact, a disease of diminished and perverted oxidation. There are not only too few red corpuscles, but there is too much water and an excess of fat."

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 23, 1884.

Deaths reported 2852 (no reports from Buffalo and Milwaukee): under five years of age, 1349; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 951, diarrhœal diseases 636, consumption 334, lung diseases 142, diphtheria and croup 72, typhoid fever 73, whooping-cough 53, malarial fevers 48, scarlet fever 29, cerebro-spinal meningitis 13, measles 11, erysipelas 11, puerperal fever four, small-pox one. From *whooping-cough*, Boston 10, New York nine, Philadelphia seven, Brooklyn and Baltimore five each, Milwaukee four, District of Columbia and Pittsburg three each, Cincinnati, New Haven, Worcester, Lynn, Springfield, Haverhill, and Fitchburg one each. From *malarial fevers*, New York 16, New Orleans 11, St. Louis 10, Brooklyn and Baltimore four each, Nashville two, Charleston one. From *scarlet fever*, Philadelphia six, New York five, Brooklyn four, Boston three, Baltimore, Cincinnati, Pittsburg, and Lawrence two each, St. Louis, New Orleans, and Providence one each. From *cerebro-spinal meningitis*, New York three, Fall River and Woburn two each, St. Louis, Cincinnati, Worcester, Providence, Chelsea, and Taunton one each. From *measles*, New York seven, Philadelphia, Brooklyn, St. Louis, and Fall River one each. From *erysipelas*, New York six, Brooklyn two, Boston, St. Louis, and District of Columbia one each. From *puerperal fever*, Nashville two, New York and Philadelphia one each. From *small-pox*, New Orleans one.

Cases reported in Boston: scarlet fever 41, typhoid fever 30, diphtheria 21, and measles two.

In 106 cities and towns of Massachusetts, with an estimated population of 1,264,429 (estimated population of the State 1,955,104), the total death-rate for the week was 20.93 against 22.4 and 20.44 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending August 9th, the death-rate was 21.9. Deaths reported 3670: acute diseases of the respiratory organs (London) 187, diarrhœa 585, measles 92, whooping-cough 75, scarlet fever 70, fever 45, diphtheria 22, small-pox (London 16, Liverpool and Sunderland two each, Hull and Cardiff one each) 22. The death-rates ranged from 14.8 in Bristol to 30.2 in Bolton; Birmingham 22.5; Bradford 16.7; Huddersfield 17.6; Leeds 23.1; Leicester 27.5; Liverpool 25.9; London 21.1; Manchester 22.1; Nottingham 22.6; Sheffield 21.9. In Edinburgh 16.5; Glasgow 24.4; Dublin 22.4.

For the week ending August 2d, in the Swiss towns, there were 52 deaths from diarrhœal diseases, consumption 30, typhoid fever 11, lung diseases eight, diphtheria and croup three, small-pox one, measles one, whooping-cough one. The death-rates were, in Geneva 18.3; Zurich 15.8; Basle 26.3; Berne 21.1.

For the week ending August 9th, in the Swiss towns there were 48 deaths from diarrhœal diseases, consumption 30, typhoid fever 19, lung diseases 11, puerperal fever three, diphtheria and croup two, whooping-cough one, erysipelas one. The death-rates were, in Geneva 18.3; Zurich 25.6; Basle 17.8; Berne 22.2.

The meteorological record for the week ending August 23d, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY FROM AUGUST 22, 1884, TO AUGUST 28, 1884.

HEAD, JNO. F., colonel and surgeon. Granted leave of absence for four months. S. O. 201, A. G. O., August 27, 1884.

WOODHULL, A. A., major and surgeon. Detailed as member of Medical Examining Board at U. S. Military Academy, West Point, N. Y., vice Captain R. H. White, relieved. Upon adjournment of the Board to return to his proper station. S. O. 201, C. S., A. G. O.

LIPPINCOTT, HENRY. Promoted major and surgeon. To rank from August 17, 1884, vice Woodward, deceased.

BARTHOLF, J. H., captain and assistant surgeon. Relieved from duty in Department of the Columbia, and to report in person to commanding general, Department of Texas, for assignment to duty. S. O. 199, A. G. O., August 25, 1884.

FINLEY, J. A., captain and assistant surgeon. The leave of absence granted him in S. O. 91, C. S., Department of Texas, extended two months. S. O. 198, A. G. O., August 23, 1884.

CRAMPTON, LOUIS W., captain and assistant surgeon. To report at Creedmoor, L. I., N. Y., not later than August 30th, as competitor, and, in addition thereto, as medical officer of the detachment of competitors. S. O. 41, Division of the Atlantic, August 20, 1884.

TAYLOR, M. E., captain and assistant surgeon. Granted leave of absence for four months, to take effect on arrival of a medical officer at Davids' Island, N. Y., to replace him. S. O. 200, A. G. O., August 26, 1884.

COCHRAN, J. J., first lieutenant and assistant surgeon. Assigned to duty at the Presidio of San Francisco, Cal. S. O. 81, Division of the Pacific, August 16, 1884.

FISHER, W. W. R., first lieutenant and assistant surgeon. When relieved by Assistant Surgeon Cochran to report in person to commanding general, Department of Arizona, for assignment to duty in that department. S. O. 81, C. S., Division of the Pacific.

MCCAW, WALTER D. Appointed assistant surgeon, with rank of first lieutenant, to date from August 20, 1884.

GYNÆCOLOGICAL SOCIETY OF BOSTON. — The next regular meeting — and the first after the summer recess — will be held at the Medical Library Rooms, 19 Boylston Place, on the second Thursday of September, at four o'clock, P. M. The profession are cordially invited.

HENRY M. FIELD, M. D., *Secretary*.

DIED, — August 25, 1884, John Homer Dix, M. D., M. M. S. S., of Boston.

BOOKS AND PAMPHLETS RECEIVED. — Text-Book of Medical Jurisprudence and Toxicology. By John J. Reese, M. D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania. Philadelphia: P. Blakiston, Son & Co. 1884.

Lectures.

SOME OF THE EFFECTS OF ALCOHOLISM.[1]

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL.

BY EDWARD T. BRUEN, M. D.,

Physician to the Hospital and Demonstrator of Clinical Medicine in the University of Pennsylvania.

GENTLEMEN, — I shall this morning ask your attention to a couple of cases which illustrate a form of disease of which we see a great deal in this hospital, namely, some of the phases of alcoholism.

In order to thoroughly understand what I am about to say, it will be necessary to preface my remarks by briefly alluding to the physiological action of alcohol. Alcohol, as far as its effect on the nervous system is concerned, is a stimulant in ordinary doses, but in very large amounts it has a paralyzing effect on the nervous centres. When alcohol is suddenly withdrawn from a person who has used it habitually, the same instability of the nerve centres is produced as when other stimulants are withdrawn. The local effect of alcohol upon the tissues is twofold: it produces sclerosis of the connective tissues of the body; the coats of the arteries and the connective tissue of the liver and kidneys are most involved; the connective tissue of the liver is markedly affected, because the alcohol being absorbed from the digestive tract is carried directly to the liver. Next to this effect upon the connective tissues alcohol establishes a universal fatty degeneration, which primarily affects the liver, perhaps for the reason mentioned above. Next to the liver the heart suffers most profoundly. The fatty deposits in the connective tissues are increased, and finally the cells lining the tubules of the kidneys become involved. Along with this, and as a part of the cause of the fatty change, we have the change in the crasis of the blood. The corpuscular elements of the blood are affected partly by the prejudicial local influence of alcohol upon the digestive tract and also by the effect which alcohol exerts on the heart. Alcohol used habitually as a beverage, and especially if taken on an empty stomach, is capable of producing an irritating effect on the mucous membrane of the gastro-intestinal canal, which may be so extreme as to amount to an actual inflammation, and there is produced a chronic intestinal catarrh, with its secretion of mucus and cells, and with an imperfect elaboration of the gastric and intestinal juices and consequent dyspepsia. The malassimilation of the food which is engendered by this chronic catarrh of the intestinal canal interferes with hæmatosis, and the corpuscular elements are poorly elaborated. These corpuscular elements also suffer from the effect upon the heart, since if the heart is weak and unable to propel the blood thoroughly throughou the system the circulation in the chylopoetic viscera is impaired, and as a result the elaboration of the blood is defective.

Alcohol has a special tendency to produce certain symptoms referable to the nervous system which are frequently incorrectly attributed to inflammation of the membranes of the brain. Alcohol has no particular tendency to produce active inflammation of the membranes of the brain, although it is liable to produce chronic nutritive changes in these membranes. What are these changes? They consist rather in thickening of the connective tissues in the membranes, and should be classed with the effects of alcohol on the connective tissues in general to which I referred a moment ago. The evidences of habitual alcoholism are found in thickening of the dura mater, in its adhesion to the skull, and often in an increase of the Pacchionian bodies. Next to this is found thickening of the pia mater, often associated with congestion of the brain. The arachnoid membrane also often presents a milky-white appearance because it is lifted up by the serous exudation beneath it. The brain undergoes hardening from the increase of its connective tissue which is associated with atrophy of the brain substance. Hæmorrhage into and softening of the brain consequent on the diseased state of its blood-vessels is possible. We are now, I think, in a position to proceed to the study of these cases.

This man, D. C., has been drinking ever since he was a boy, and will illustrate one of the effects of both acute and chronic alcoholism, namely, delirium tremens. He was admitted on the 18th of this month (five days ago) in the condition known as alcoholic delirium. In addition he had epileptiform convulsions, and he did not sleep from the time of admission until the night of the 21st. During this period of insomnia he was subject to the peculiar delirium of this affection, seeing spectres, shapes, animals, etc., and was exceedingly violent and anxious to get out of bed. If he had been allowed to do so he probably would have injured himself or others in his efforts to get away from the horrors which surrounded him.

As far as the diagnosis is concerned it is usually based on a good history. Insanity is characterized by delusions, not mere terrors or hallucinations. Acute alcoholic coma often precedes an attack of delirium tremens. A good history is perhaps about the best guide, unless some of the contents of the stomach is obtained and analyzed. The uræmic condition is the one which usually has to be eliminated. Uræmia, as a rule, is not attended with the fanciful delirium of delirium tremens, but more often with stupor and coma. The next thing to be done after obtaining the history is to examine the urine and the condition of the heart. Usually, in chronic renal disease the heart is hypertrophied and the examination of the urine will give important data. In reference to the diagnosis between delirium tremens with stupor and apoplexy the only point which is of special value is the recognition of some local paralysis. A patient suffering from alcoholic coma suffers from a general paralysis, or rather a paresis, but in a patient suffering from hæmorrhage into the brain there is usually paralysis of the arm, leg, face, tongue, or some other part.

What is the next most important point clinically? It is to determine whether the attack in which the patient is seen is the first or whether there have been many attacks. This has an important bearing on the treatment. Usually this information can be obtained without much difficulty. We shall suppose a case of a man on a drinking bout; he has not eaten food, and during this "spree" he has suddenly stopped drinking, or while drinking he has been subjected to some unusual excitement or acute disease, and delirium tremens has supervened. It is the first or second attack. In such a case, as also in the one before us, it is reasonable to infer that the extreme effects of alcohol upon the

[1] Reported by William H. Morrison, M. D.

tissues are not present. The heart is probably sound, and the connective tissues not especially involved.

What shall be done? The most important thing to remember is that delirium tremens is a disease which is usually self-limited. I have seen people killed by remedies because the physician forgot that this was a self-limited disease. The patient should in the first place be put in a room by himself, under conditions of perfect quiet. He should have an attendant to sit by him during the entire time that he is under treatment. The duty of this attendant should be to administer to the patient nourishing food at short intervals, combined with such stomachic stimulants as will increase the ability of the patient to assimilate it. This food should be of the most nourishing and assimilable character, and should consist of such articles as strong beef broths strongly impregnated with pepper, and eggs beaten up with milk.

If the patient cannot sleep there are two or three measures which can be adopted. One of these is to use bromide of potassium and chloral. Feed the patient during the day, and when night comes give five grains of chloral every five minutes until twenty grains have been taken, and the cumulative effect of these successive doses will often induce sleep when a single dose of twenty grains would have no effect. With the divided doses of chloral one drachm or more of bromide of potassium may sometimes be combined. If this treatment produce a couple of hours or more of sleep, then the same amount of chloral may be repeated. I do not recommend the large doses of twenty grains repeated every two hours until a drachm is taken, for the heart may be weak from paralysis of innervation although not from degeneration, and it may be arrested by too large a dose of chloral.

Suppose, however, that the patient does not sleep under the use of chloral and bromide of potassium, what shall be done? In an acute case in a reasonably strong person in whom the pulse is not over 100 per minute the following plan may be adopted: Give three doses of the following mixture at intervals of two hours: —

℞ Pot. et antimonii tart. . . . . gr. ¼th.
Tinct. opii . . . . . gtt. v. ad. viij.
Aq. camphoræ . . . . . ʒi.

This will often be successful not only in the alcoholic delirium, but also in forms of delirium in the sthenic forms of fever. The depressing effect of the tartar emetic if excessive can be counteracted by a little alcohol. It is much safer to employ this treatment than to give morphia hypodermically, or two or three large doses of laudanum, as is frequently recommended. I deprecate the free use of opium in cases of acute delirium tremens.

There is another thing which may be done. Often the patient, instead of being in a state of delirium, will have "the shakes," and be on the verge of delirium tremens. I am still speaking of acute cases. Such a patient will come to you and state that he has been on a spree; that he cannot sleep; that he hears sounds and sees sights; that he is nervous, and has no appetite. Here, again, I should deprecate the use of opium. Such a case should be treated on the same principles which I have already given. The excitement of the nervous system must be allayed, and sleep must be induced. To increase the appetite I often use a prescription like the following: —

℞ Morphiæ sulph. . . . . gr. i. vel ij.
Tinct. quassiæ,
Tinct. calumbæ,
Tinct. cinchonæ comp.,
Tinct. gentianæ comp., } . . . . . ää ʒi.

Sig. One teaspoonful three or four times a day, one hour before meals.

The effect of the combination of two or three bitters is often better than that of either one alone. The use of morphia, in small amounts, allays the irritability of the stomach, does not interfere with digestion as much as opium, and in the above dose it acts as a species of stimulant to the nervous system.

Let us now turn to the next patient, P. B., who was admitted six days ago. He has also been drinking, more or less, ever since he was a boy, but in his case the attack of delirium tremens supervened nearly a week after he had ceased to use the alcohol. I shall, therefore, take this opportunity to allude to the chronic form of delirium tremens. What should be done? The patient should, as before, be put in a room where he will have perfect quiet, and alimentation should be, as before, of primary importance. In these cases the weakness of the heart is to be feared, and it is, therefore, not proper to use chloral or the bromides so freely as in acute cases. The patient should be fed during the day, and at night be given a single good dose of morphia hypodermically. If the pulse should be very weak, and above 100 or 120, it will be necessary to administer small amounts of alcohol and also digitalis, because you wish to avoid all tendency of the stupor to pass into coma. Sometimes small stimulant doses of opium every three hours are useful. Coma frequently supervenes because the weak heart fails to propel the blood thoroughly throughout the body, and especially through the brain, and there is thus produced a tendency to venous congestion of the brain. Digitalis prevents this by bettering the circulation; alcohol also assists this end, and is to be used with judgment.

Leaving this matter of delirium tremens, let us consider another aspect of this second case. Mark the flabby features of the patient, the patches of acne rosacea about the nose and mouth. Since the subsidence of the delirium tremens he has been suffering with cramps in the stomach, slight jaundice, and congestion of the lungs, and the tongue has been thickly covered with fur; some vomiting in the morning, slight vertigo, and dull headache. His pulse has been 140 per minute, almost too weak to be counted, and the first and second sounds of the heart have been almost inaudible. The explanation of these symptoms is connected with the lesions of chronic alcoholism to which I alluded at the beginning of the hour, namely, the degeneration of the heart and paresis of the nervous system. The congestion of the lungs was due to the weak heart failing to propel the blood through them, and it was recognized by the harsh breathing, the presence of a few râles, and the impairment of resonance on percussion. The jaundice and the furred tongue was attributable to the imperfect circulation of the blood through the liver and digestive tract. In some of these cases albumen is found in the urine, although in this particular instance it was absent. These patients sometimes have convulsions, but the explanation of their origin is entirely different from that of the convulsion which the first patient had.

Patients suffering with delirium tremens may have convulsions which are epileptiform in character, and

due simply to the effect of alcohol on the nervous system. In our first patient the convulsions were probably of this character. They may also have convulsions which are uræmic, due to suppression of the renal function.

How is the diagnosis between these two forms of convulsions to be made? It is very simple. The uræmic convulsion is preceded by a reduction in the amount of or suppression of the urinary secretion and the presence of albumen in the urine. In the epileptiform convulsion there may also be albumen in the urine, but the amount of secretion is nearly normal; the skin is moist; the pupils are usually not contracted; and the breathing is not very deep or stertorous, for if the patient is suffering from uræmia there is a tendency to take deep breaths in order to aerate the blood. I know of no more constant single sign of approaching uræmia than this deep breathing. With the epileptoid convulsions the patient may breathe naturally or, if in a state of coma, he may breathe slowly, but there will not be this deep stertorous form of breathing.

What is the proper treatment of a case subject to the effects of alcohol with congestion of all the internal organs and degeneration of the tissues? The treatment of this case is somewhat typical. The first thing to be done is to administer stimulants to act upon the organ whose function is most important, namely, the heart. This patient was given alcohol and digitalis. A saline purge was also administered. As soon as the circulation was somewhat reëstabiished he was given a small dose of calomel combined with the benzoate of ammonium. This drug is a very valuable agent in congestion of the liver, with slow digestion. The effect of the ammonium is anti-plastic and resolvent in cases of slight catarrh of the duct, and at the same time it favors the elimination of the products of retrograde metamorphosis of the tissues, which are carried off by the urine. The proper plan of using this drug is to give ten or fifteen grains in the evening, to be followed in the morning with a purge. In some cases it is necessary to repeat this treatment every other day for a week. Although it is designed to substitute this drug for calomel it may be associated with calomel if desired.

The bitter tonics are useful according to the prescription already given, omitting the morphia.

Under what circumstances do these alcoholic affections become dangerous and the prognosis unfavorable? Broadly speaking it is when the tissues are found to be in a state of degeneration. A careful study should be made of the kidneys, the heart, the arteries, the liver, and digestive tract. There is also grave risk of acute pulmonary complications, such as pneumonia. Even in acute alcoholism the patient may never rally from the primary insensibility.

There is one more matter to which I desire to allude, and this takes me back to a point to which I referred at the beginning of the hour. Patients are often supposed to suffer from meningitis because the cerebral *tâche* can be produced. You see the red line which appears when I draw my finger across the abdomen. Sometimes this line will follow the passage of the finger across the forehead. These *tâches* appear in typhoid fever, in typhus fever, or in conditions analogous to the typhoid state. The point which I wish to impress is that the *tâche* does not always indicate cerebral inflammation. It can be produced by weakness of the heart and venous congestion, so that when the blood is pressed from the capillaries by the passage of the finger across the skin the capillaries are slow in again filling up. The *tâche* is, therefore, not always an indication of cerebral inflammation, and the cerebral symptoms present in cases of alcoholism are not, as a rule, attributable to acute inflammatory conditions.

A CASE OF SUPPOSED EXTRA-UTERINE PREGNANCY TREATED BY ELECTRICITY.

BY FANNY BERLIN, M. D.

ALTHOUGH cases of extra-uterine gestation are by no means a rare occurrence, and reports of such not at all scanty, the fact always remains that the anomaly is of so interesting and grave a nature that a detailed report of another case may not be without interest to the profession. I here wish to state that I am greatly indebted to Dr. J. R. Chadwick for his courteous advice to publish the case, as well as for his kind suggestions with regard to the literature of this subject.

Mrs. Caroline H., aged forty, has given birth to eight children, five at full term and three prematurely; miscarried once. Always menstruated very profusely, and since the birth of her last child, in 1881, very irregularly, about once in two or three weeks. In May, 1882, she passed two pieces of membrane from the uterus, after much pain. Her attending physician at that time told her it was a miscarriage. In December of the same year she passed a cast of the uterus, which was accompanied by a great deal of bearing-down pain and considerable flowing. This membrane she brought to the New England Dispensary for Women and Children during one of the days of my attendance there. She complained of feeling miserable generally, but on internal examination nothing abnormal could be ascertained, except a slightly retroverted, apparently normal-sized uterus. The membrane presented a perfect cast of the body of the uterus from the commencement of the Fallopian tubes to the os internum.

In January, 1883, she menstruated for four days. The last of February she passed another cast of the uterus, similar to the first one, which she again brought to the Dispensary, but as she was flowing quite a little then she was sent home without any internal examination, and as she lived at a very great distance from the Dispensary she was advised in case of need to call a physician who lived near her residence. From that time until she came again under our observation she remained under the care of Dr. E. G. West, and I will present here in a condensed form the report of the case while under his charge, with which he has kindly furnished me: —

On the 6th of March, 1883, Dr. West was called to see the patient, who was in bed, suffering from severe colicky pains in the abdomen, particularly in the left iliac region. She was flowing, which continued for the next few days. Her temperature was 101° F.; pulse between 100 and 110 per minute. An internal examination caused so much pain that it could not be made thoroughly. No distinct mass was felt, but "local peritonitis" was evident. She was suffering greatly from severe ischuria and pain during defecation. The treatment consisted of morphia administered internally and

subcutaneously when there was an exacerbation of pain, hot vaginal douches, and flaxseed poultices to the abdomen. Under this treatment the symptoms abated gradually until the 21st of March, when she was again taken suddenly with an exacerbation of all the symptoms which were present on March 6th. This time she suffered more from the difficulty in urination and during a movement of the bowels, as this latter process was sorely complicated by the presence of hæmorrhoids.

On the 5th of April there was another very severe exacerbation of all the symptoms, although the remission during the last two weeks was not as great as that during the first two attacks. On the 15th of April Dr. West made an internal examination, and then *for the first time* discovered a tumor the size of the body of the uterus in the posterior cul de sac, which seemed fixed and attended by considerable pain when manipulated. The doctor watched the symptoms for two weeks longer, and as there was no change in the condition of the patient, and it was about time for another periodical exacerbation, he called Dr. J. R. Chadwick in consultation on April 28th, and called me on the 29th. We all met on the 1st of May, and found the following condition of affairs: —

The patient looked quite anæmic; pulse good, normal. No rise in the temperature of the body. The abdominal walls were very relaxed and easily permitted us to feel through them a tumor the size of a uterus in the fourteenth week of pregnancy. It was located more towards the left hypogastrium, and was of roundish shape, of elastic consistency, with a nodular projection on its left side, which seemed especially sensitive to pressure. On internal examination the posterior cul de sac, especially its left half, was found to be occupied by a mass, which crowded the uterus forward and towards the right side. Combined internal and external examination allowed the uterus to be distinctly felt in front of the mass and pushed by it to the right side. The cervix uteri was almost obliterated, and tightly pressed against the symphysis pubis. The uterus seemed larger than normal, although the sound for measuring the cavity was not used at that time. The surface of the mass felt somewhat uneven; there was no decided fluctuation to be felt, except that one spot posteriorly, about the size of half a dollar, with rough and nodular edges, gave the feeling of being very much thinner than the rest of the mass, and through it distinct fluctuation could be felt. In several places on the surface of the tumor pulsations were noticeable. The same condition was ascertained through examination made by the rectum. The patient complained of nausea and faint feelings at every attempt to rise. She thought herself pregnant, as many of the symptoms reminded her of her previous pregnancies.

Taking into account the whole course of the woman's illness, the irregular hæmorrhages, the discharges of the deciduæ, the violent, colicky pains, the presence of the elastic tumor, the enlarged and separately defined uterus, the symptoms of local peritonitis, and last, but not least, the woman's own belief that she was pregnant, the diagnosis of extra-uterine pregnancy, probably graviditas tubaria, in the fourth month, was suggested by Dr. Chadwick, and electricity as a means for the destruction of the fœtal life before another exacerbation of the symptoms set in agreed upon. For this purpose the patient was transported to the New England Hospital for Women and Children, and the following day the application of electricity was begun. The first application was given with the constant current on the 2d of May. One pole was applied to the mass through the vagina and the other externally through the abdominal walls. The strength of the current varied from two to eighteen cells, and the interruptions were quite rapid. The time during which the galvanism was applied lasted twelve minutes. She complained bitterly of its hurting her, especially every time the number of cells was increased. The application was repeated the following day, but the patient commenced to flow soon after it quite profusely, and it was considered best to wait until the flow had subsided. The 13th of May the flow ceased and galvanism was again resumed, and the applications repeated the 15th, 17th, 19th, and 22d. Neither during nor after these applications could any change be noticed in the shape or size of the mass, or in the pulsations of the vessels. It was decided then to cease with the applications of galvanism and await further developments in the case.

The 1st of June menstruation set in again. She was at that time feeling quite comfortable, her general health had improved greatly, the pains had almost entirely disappeared, but the tumor still remained unchanged. At about that time the uterine sound was carefully introduced and the uterine cavity found to measure four inches. The attending physician at the hospital at that time, Dr. Helen Morton, into whose charge she had passed, ordered her 0.5 of iodide of potassium, to be repeated three times daily, which she continued to take until the middle of September.

The 9th of July she was dismissed from the hospital to be under outside observation. I saw and examined her at her home the 11th of August, and found the mass decreased to about half its former size. A second examination, on the 25th of August, showed it still decreasing in size. On the 19th of October nothing but a small portion of the former mass could be felt in the posterior cul de sac, towards its left half, in the shape of a soft, flat, glandular-like body, rather sensitive to the touch. The uterus was anteverted and still somewhat larger than normal. Extending from its left and upper end was to be felt a sausage-shaped body, the thickness of a finger, of a distinctly fluctuating character, whose end lay closely over the flat, glandular body above mentioned. It gave the impression of being the left Fallopian tube, probably dropsical. The 9th of February, 1884, Dr. Chadwick kindly examined the woman with me and corroborated the above-described condition of the pelvic organs.

The case is of interest principally for two reasons: (1.) With regard to the diagnosis: Was it justifiable to suppose extra-uterine gestation as the existing condition in this case? The diagnosis of extra-uterine fœtation in the first three or four months is under any circumstances difficult to make with absolute certainty. It is interesting to follow the different authorities with regard to this question. Thus, for instance, Parry, in his excellent work on Extra-Uterine Pregnancy, expresses himself: "If with the woman's conviction that she has conceived are associated colicky pains, located in the hypogastrium, or one iliac fossa, of the most severe character, producing collapse more or less profound, with or without syncope; if these pains come on in paroxysms or have violent exacerbations at more or less regular intervals, with a bloody discharge from the uterus, the existence of extra-uterine pregnancy should always be suspected. If symptoms of abortion super-

vene with the discharge of a decidua, or if the phenomena of rupture of the cyst follow the symptoms just enumerated, it is the duty of the woman's medical adviser to treat her as if she were carrying an extra-uterine child."[1]

According to Hennig[2] the diagnosis of graviditas tubaria is composed of two parts: (1) the recognition of existing pregnancy, and (2) of the "seat" of the impregnated ovum. In most cases pregnancy can be recognized only through probable symptoms, as it rarely reaches that time when all the pathognomonic symptoms are present, namely, fœtal movements, pulsations of the heart, recognition of fœtal parts. Even the discharge of a decidua is not an entirely sure sign, as membranes are discharged during different diseases of the uterus and general disturbances.

Wyder[3] describes a case of extra-uterine gestation, and gives a detailed account of the macro- and microscopical appearance of the discharged decidua. He asserts that the mucous membrane of the uterus, when pregnancy, intra- or extra-uterine, exists, has a specific structure, which is manifestly different from the structure of dysmenorrhœic membranes, or membranes discharged when endometritis exists. It consists mainly in the different form of the elements composing the interglandular tissue; this latter under normal and other pathological conditions consists of small, round cells, with scanty protoplasm, whereas it presents even in the commencement of pregnancy a very characteristic, large, variously shaped cell, surrounded by an abundance of protoplasm. Wyder thinks that by means of the examination of such a membrane alone the diagnosis of pregnancy can be accepted or excluded. The thick, fleshy membranes which our patient discharged from the uterus presented at least macroscopically the same appearance as the membrane described in Wyder's case. Unfortunately no satisfactory microscopical examination was made, and it therefore cannot be utilized as a positive symptom. However, Ernst Fränkel[4] goes so far as to deny the existence of any pathognomonic symptom in extra-uterine gestation, as all the symptoms belonging to that condition are very variable, except, of course, in cases of advanced pregnancy, when together with an empty uterus the presence of a fœtus can be ascertained. Ruge[5] and Möricke[6] have both demonstrated the existence of the specific looking interglandular cell in membranes discharged during other conditions besides extra-uterine pregnancy, — in endometritis, especially of the chronic form; in endometritis complicating myoma; also in membranous dysmenorrhœa. Thus we see that this one symptom alone of extra-uterine gestation is only of importance in confirming the diagnosis when the anamnesis, course, and present clinical condition of the case present the other rational symptoms of this anomaly, and also when other affections with which it may be confounded can be excluded. These are: hæmatocele, rapidly developed ovarian cyst, and retroverted, pregnant uterus. This latter condition could with certainty be excluded in our case, as the uterus could distinctly be felt in front of the mass, and subsequently, by introduction of the sound, was found to be empty. The very short time within which the tumor appeared, as there was nothing abnormal to be felt in December, and the attending physician noticed a "swelling" for the first time the middle of April, would speak against its being an ovarian cyst. Then, again, the uterus was enlarged, a condition not common in ovarian cysts, but a valuable symptom for extra-uterine pregnancy. Further, the general symptoms of the case — the hæmorrhages and exacerbations of pains, the symptoms of the bladder and rectum — all these speak distinctly and decidedly in favor of extra-uterine gestation.

The differential diagnosis between extra-uterine pregnancy and hæmatocele is not so easy to make, and the two have frequently been confounded by very experienced gynæcologists. Scanzoni[7] says there are no general signs of recognition between those two affections on account of the great variability of the symptoms of extra-uterine pregnancy. But here also we can take recourse to the difference between the separate signs. The uterus is enlarged and separated from the tumor in extra-uterine gestation, but is almost always blended with the tumor and not enlarged in hæmatocele. Of great importance is the character of the pains, intense, colicky, and in pretty regular paroxysms, — signs not prominent in hæmatocele. If in addition to these differential points we add the woman's own belief that she was pregnant, — and this is certainly not to be overlooked in a woman who has given birth to so many children, — we may, with a great deal of certainty, exclude hæmatocele from our diagnosis.

The second point of interest in the case is with regard to the treatment pursued, and the satisfactory result which ought, in all probability, to be attributed to it. It is a singular fact that this mode of treatment, although first used by Dr. T. G. Allen fifteen years ago for this purpose,[8] has had, until quite recently, so few followers who were willing to try its efficacy. Hardly any mention of it is made in the literature on this subject published in Europe. Thus in a report of twelve cases of extra-uterine pregnancy by W. A. Freund[9] the author advises for treatment in the first three months puncture of the sac and injection of morphia. If the sac rupture spontaneously in consequence *no* operation is advised, and as such cases, in the author's experience, only rarely die, even when the symptoms are very alarming, he does not advise operative interference, and simply treats the threatening symptoms of anæmia and peritonitis. Mention is made in Case IX. of a weak current of electricity being applied to the tumor by the house physician, after which the patient perceived no more movements, the tumor decreased markedly in size, and the woman recovered. In this country, however, within the last few years, considerable attention has been given by prominent men in the profession to the use of electricity in extra-uterine pregnancy. Dr. Henry J. Garrigues, in a paper published in the Transactions of the American Gynæcological Society for 1882, gives an account of a case of his own, and a synopsis of other cases scattered through literature, where electricity has been used. His conclusions are that it is a very efficient and safe agent for the arrest of the development of the fœtus in the early months, and that it seems likely that the same treatment might be used at any period of fœtal

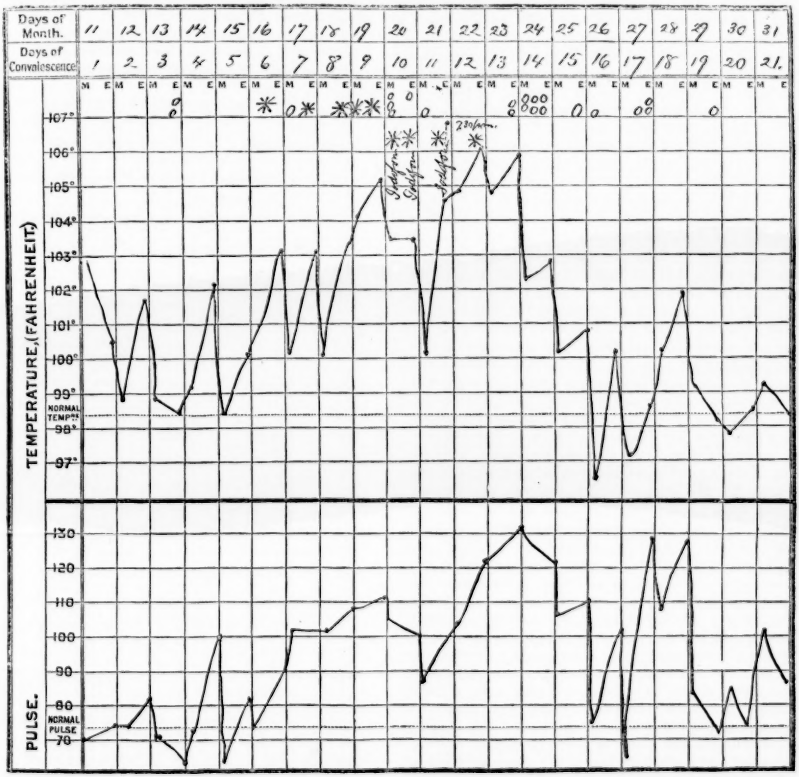
life. Dr. T. Gaillard Thomas, in the history of twenty-one cases of extra-uterine pregnancy,[1] gives the account of six cases in which electricity was used. All of these cases recovered. And, finally, Dr. A. D. Rockwell has published seven cases of the same anomaly, all successfully treated by galvanism.[2] In his cases, as well as in most of Garrigues' and Thomas's cases, the change of the size and shape of the sac could be noticed either immediately or in a short time after the application of electricity. We could not perceive any change either in size or shape of the mass until nearly three months later. But the mass ceased to increase in size from the day the current was applied; the subjective feelings of the patient commenced to improve very soon after, and menstruation has appeared regularly every four weeks since.

ON THE USE OF IODOFORM INSUFFLATION WITHIN THE UTERUS IN PUERPERAL SEPTICÆMIA.[3]

BY W. E. BOARDMAN, M. D.

MUCH has been said, volumes have been written, since the middle of the eighteenth century, upon the affection known, until late years, only as puerperal fever. Indeed, it may be said that no subject connected with the process of parturition has given rise to greater diversity of opinion as to its origin, nature, and treatment. Even at this day our medical journals are overflowing with the diverse views of eminent practitioners, the individual opinions of many of whom ordinarily are accepted as law in matters appertaining to the theory and practice of obstetrics. This fact, perhaps, of late years, has never been more succinctly emphasized, to our minds, than during the recent discussion of the subject by the very distinguished members of the New York Academy of Medicine. Yet I think I do not err when I state that, in the matter of the origin of the disease, the position taken by Dr. Thomas is sustained by most authorities.

At all events I am satisfied to range myself upon the side of those who believe that there is no essential puerperal fever; that the affection is a septicæmia; that the septic germs are micro-organisms which do not exist normally in the lochia or within the genital tract, but are developed in the organic substances of putrefaction under varying conditions; that these germs find an entrance into the system so as to induce two types of the same disease essentially, which may develop either separately or in common, according to the fact whether the initial lesion is one of the lymphatics, or of the veins, or of both together. Acting upon this theory it has been my practice, in the way of treatment, to attack first the original seat of the septic process, with the view of arresting the germ development within the uterus or vagina, and then to endeavor to correct the evils already induced in the system. In my previous terms of service at the Lying-In Hospital it was my custom to rely upon carbolic acid for the former purpose; but continued experience appeared to demonstrate that this agent did not always accomplish the work which most obstetricians claimed for it, and, during my service in the summer of 1883, I determined to make use of some other remedy, should the occasion seem to arise. In July such a case presented itself, and I beg leave to offer the following record of an undoubted case of puerperal septicæmia in which the septic poisoning was arrested by the insufflation of iodoform within the uterus and throughout the vagina, after ordinary methods, including intra-uterine injections of carbolic acid, had failed to stop the progress of the disease, as indicated by the gradual increase in the intensity of the unfavorable symptoms.



M. H., single, primipara, entered the Boston Lying-In Hospital, and was confined early in the morning of July 11, 1883. The labor was normal, vertex presentation, O. R. A., the child weighing six pounds. The perinæum was intact, and before her discharge the uterus was found to be slightly anteflexed, three inches in depth, with the cervix lacerated bilaterally.

Referring to the accompanying clinical chart it will be observed that, from the first record, taken on the morning following the completion of the labor, the temperature showed an unfavorable condition of things. During the first two days this was reduced temporarily under the use of sponge baths. On the third day it was noticed that the lochia were scanty and rather foul. Milk appeared in abundance, necessitating an efficient supporting of the breasts. On the sixth day, at eight P. M., an intra-uterine injection of a two per cent. hot carbolic solution was given on account of the offensive lochia and gradually increasing temperature, which then marked 103.2° F. A few shreds only came away, but the temperature fell to 102° F. On the seventh day the intra-uterine injection was repeated at evening, when the washings were reported to have been rather muddy and containing a few shreds. A chill followed this procedure, and it was ascertained that she had previously had "chills and fever," though the history in this respect was obscure. On the eighth day the same course was followed, except that the chill was prevented by the use of a subcutaneous injection of morphine. Still the pulse and temperature continued to rise, and on the next, the ninth, day, intra-uterines were given both morning and evening, and each furnished muddy washings with a few shreds. Yet at evening on this day the temperature reached 105.4° F. and pulse 114.

On the morning of the tenth day the temperature had fallen somewhat, to 103.6° F.; but the injection gave the same washings as before. The injection was supplemented by insufflation within the uterus and vagina of iodoform, and at evening the temperature was 103.5° F., and the insufflation of iodoform was repeated, the uterus having been thoroughly washed out with the hot carbolic solution. On the following morning, it will be observed, the temperature had fallen to 100.2° F., and the pulse had dropped from 102 to 89. On account of the patient's favorable condition and the character of the lochial discharge, the intra-uterine treatment was omitted, but repeated at evening. It will be noticed that on this evening visit the temperature had again risen to 104.6° F., and at 7.30 P. M. a temperature of 106.8° F. was recorded. At the same time the pulse began to increase in frequency, and the respirations were 30 in the minute. But the record affords good reasons, apart from the intra-uterine disease, to account for the sudden unfavorable turn of affairs. Early in the morning a small erysipelatous blush was observed over the lower sacral region. In the afternoon she complained of pain in right chest, with slight cough and viscid and reddish sputa. Ex-

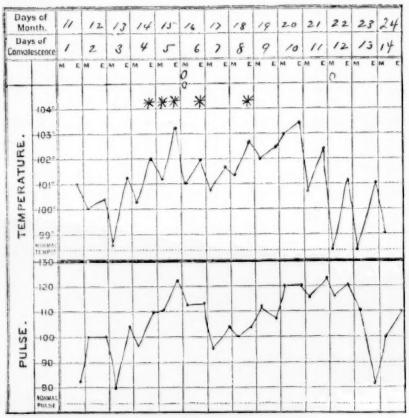
[3] Read before the Obstetrical Society of Boston, April 12, 1884.

amination of the chest detected sibilant râles in the right mammary region and at the right base, and an explosion of fine râles after coughing; no dullness on percussion. At evening of this, the twelfth, day, the ninth and final intra-uterine injection of carbolic solution was given, the fluid coming away clear, and therefore the insufflation was omitted. The temperature was 106° F., and on the following day at the same hour 105.8° F., with a pulse of 30. From this time the lochia were no longer offensive, and ceased to appear on the fourteenth day; but the condition of the patient became and continued to be alarming for several days: in fact, it was believed that she could not possibly survive, not from active sepsis, however, for this process evidently had been arrested promptly by the iodoform. Her serious illness during these days was obviously due to the affection of the lungs and a succeeding peritonitis and diarrhœa, all of which finally induced such an extreme condition of collapse that she must have died had she not been favored by the indefatigable attention, both night and day, of Dr. Worcester, the senior house officer.

Note. The sign o indicates an injection. * indicates an intra-uterine injection of a two per cent. solution of carbolic acid. In the succeeding charts * indicates an injection of a solution of corrosive sublimate, one to two thousand.

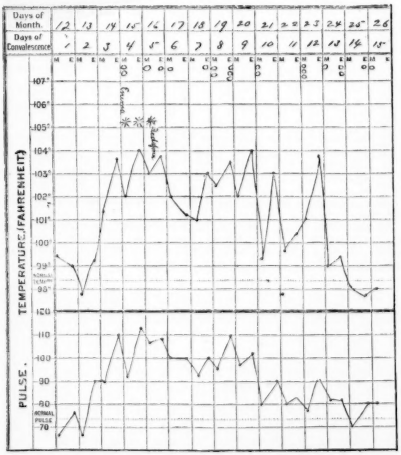
While the history of this case in all its details of symptoms and treatment forms a most interesting record, I have not thought it best to detain the Society by its recital at length, but have endeavored to present briefly the salient points which serve to illustrate to my mind the very marked beneficial effects which were obtained by the employment of iodoform within the uterus where carbolic acid had failed to arrest the septic process, a procedure, I may add, which to my knowledge had not then been employed by others.

Reviewing the record we find that for nine days the patient gradually became worse, and evidently from septicæmia; that the intra-uterine injections of carbolic acid and accompanying internal treatment appeared to have no effect in arresting the process within the uterus, as evidenced by the character of the washings and the symptoms; that on the morning of the tenth day the insufflation of iodoform was done, with the result of an evening temperature 0.1° F. less than in the morning. At evening the iodoform was employed again, and on the following morning the temperature was 100.2° F. and pulse 89. On the evening of this day the washings had improved and iodoform was employed for the last time, though another intra-uterine injection



was given on the next day, on account of the unfavorable change in the patient's condition, and with the fear that sloughing within the uterus had recommenced; but the results showed that the change was due to other and new processes of disease unconnected with the uterus, for the lochia now rapidly diminished and disappeared altogether on the fourteenth day, while the new affections ran their course with alarming symptoms, which, however, she survived and was discharged well August 9, 1883, thirty days after entrance.

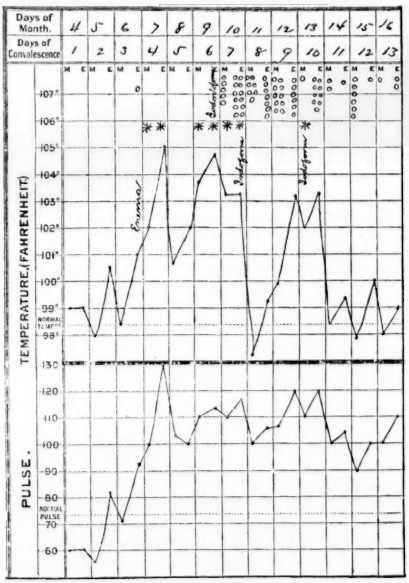
Remarks. As to the best method to be employed in order to do the insufflation, *cito, tuto, et jucunde*, I would recommend the use of a large-sized bottle, a modification of the one which has been devised by our associate Dr. Forster; but in place of the flexible efferent tube it is better to use a more rigid one with a terminal opening. With this one will be sure to reach the fundus and to cover the entire interior of the uterus with the powder. With the proper arrangement of the tubes within the bottle, and avoiding undue force in the compression of the bulb, there can be little or no danger of forcing air into the uterus. As to the danger from the use of iodoform in these cases, I think a review of the reported cases of poisoning by this agent will not deter us from the future employment of a promising method of dealing with this very dangerous malady to the lying-in woman.



During a recent term of service at the hospital for the first quarter of this year I abolished the use of carbolic acid altogether and substituted a solution of corrosive sublimate 1 to 2000. For obvious reasons this season of the year has usually been more prolific in septicæmic cases, many of which have been fatal. This year, however, the hospital has been comparatively free from the disease, and I am persuaded that the immunity has been due to the lavish employment of the sublimate solution which was required to be used for the toilet of the physicians, nurses, and patients upon all and every occasion, and for douches. In spite, however, of the utmost care, some few cases gave evidences of septicæmia which the sublimate solution did not arrest, and in these I resorted to the use of iodoform by insufflation, with what appears to me to have been very happy results. In a few others the iodoform was employed at once with the apparent effect of arresting the septic process in its incipiency. Possibly in these latter cases the sublimate solution or, may be, a carbolic acid injection might have produced equally good effects. The brief records of some of these cases are presented herewith, together with charts of the temperature and pulse in each. All appeared to me to be undoubted cases of septicæmia, and it is an interesting and instructive fact to be observed from a study of them that the septic poisoning evidently was arrested either at once or in a very brief time. The charts of Driscoll and Crowley apparently seem to contradict this view, but the clinical records show that with the former the second rise of the temperature and pulse was due to the development of a very serious, indeed, usually fatal, skin affection, which Professor White kindly inspected and diagnosticated as impetigo herpetiformis or herpes impetiginiformis, while in Crowley's case the subsequent elevation was due to the development of a cellulitis or peritonitis, or both, for which she still remains in the hospital.

In none of these cases were any symptoms of iodoform poisoning presented, unless the skin affection be classed under this head, and I understood Dr. White to state that this could not be due to anything of the kind. While I do not claim that these cases prove the point which is the basis of the paper, yet it seems to me that we may receive a suggestion from the recital which perhaps will aid us in dealing with this protean malady incident to the parturient period.

Maggie Driscoll. Labor normal. Lochia became offensive on the fourth day: uterine and ovarian tenderness quite marked, severe headache, loss of appetite, considerable nausea, and great prostration. Washings from intra-uterines were muddy. Treatment: Intra-uterines of corrosive sublimate 1 to 2000 and iodoform into uterus, peptonized milk, koumyss and beef tea, brandy, enemata of milk, brandy, and laudanum: Recovery. Skin affection, — impetigo herpetiformis.



Katie Crowley. Labor normal. On second day developed abdominal tenderness, which increased in

severity, also tenderness over uterus. Rigidity of abdominal muscles, much headache; lochia remained normal. Nausea, tympanites, considerable perspiration. Treatment: Intra-uterines of corrosive sublimate 1 to 2000, iodoform into uterus; stimulation, liquid diet ad libitum; morphia (one quarter grain) suppositories. Cellulitis or peritonitis on right side.

Elizabeth Page. Labor normal. On fourth day developed uterine tenderness, which continued during the following ten days. Lochia were normal and remained so throughout sickness. Diarrhœa began on seventh day and continued for a week in spite of treatment. On eighth day she vomited once, but not after that. Uterus was large and boggy. Washings from intra-uterines contained a few shreds. These, with great prostration, were the principal symptoms. Treatment: Intra-uterines of corrosive sublimate 1 to 2000, and iodoform blown into uterus; peptonized milk, beef tea or brandy every hour; same per enema. Diarrhœa mixture of tr. opii and astringents. Chloral and morphia at night. Poultices and turpentine stupes to abdomen. Recovered.

Nina Clare. Labor normal. On the second day developed tenderness in left ovarian region and headache: lochia became scanty and offensive. On seventh day had a chill: appetite poor: considerable thirst. On the ninth day diarrhœa began, but was soon controlled. Considerable prostration. Vomited on eighth and ninth days. Washings from intra-uterines contained few shreds. Treatment: Intra-uterines of corrosive sublimate, 1 to 2000, and iodoform blown into uterus. Stimulation. Liquid diet ad libitum. Opium and astringent mixture for diarrhœa. Recovery.

Hospital Practice and Clinical Memoranda.

TWO CASES OF HÆMORRHAGE INTO THE PONS VAROLII.

BY R. B. BONTECOU, M. D., TROY, N. Y.

In a former number of the *Boston Medical and Surgical Journal* is an article by Dr. Hurd on Apoplexy of the Cerebellum. It brought to my mind two cases, occurring in my practice, of apoplexy of the pons Varolii in brothers of about the same age. From the rather uncommon locality of the lesion it may be well to place them on record for the benefit of statistics.

The first case, E. R., was a man aged forty-seven years, six feet high, weight about two hundred pounds, married, and keeper of a saloon and restaurant, and of previous good health and history, except occasional slight attacks of gout. Without any known premonitory symptoms he was suddenly seized, on March 3, 1853, with coma and complete abolition of sensation and motion; respiration was difficult and irregular, and deglutition impossible, and he expired in about an hour and a half after the attack.

Autopsy, twenty-four hours after, revealed nothing pathological in the cerebrum, cerebellum, medulla, or membranes, but upon section of the pons a clot was discovered, about the size of a cherry, pressing on the floor of the fourth ventricle.

Second case, W. R., brother of the first, aged fifty-six years, of medium stature and development, married, and by occupation a saloon-keeper, personal and family history good, was seized suddenly, without any known premonitory symptoms, March 25, 1870, with coma and complete loss of sensation and motion, and expired in an hour and a half from the seizure.

Autopsy, twelve hours after, revealed a clot in the centre of the pons, the size of two cherries, tearing and disorganizing its structure to a considerable extent. No other pathological changes were discovered within the cranium.

In a long practice, with rather extensive opportunities for post-mortem observations, I have found only these two cases of apoplexy of the pons, and, occurring as they did in brothers, think it may be of interest to some. These persons were not considered as intemperate, although the nature of their occupation undoubtedly led them to the habitual use of stimulants.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M. D., SECRETARY.

APRIL 12, 1884. The President, DR. C. ELLERY STEDMAN, in the chair.

DR. INGALLS read a paper on Some Cases in Pædiatrics, which was briefly discussed by Drs. Abbot, Rotch, and C. E. Stedman.

EXTRA-UTERINE PREGNANCY.

DR. CHADWICK read a paper, written by Dr. Fanny Berlin, on a Case of Supposed Extra-Uterine Pregnancy.[1]

DR. W. F. WHITNEY, present by invitation, said that he had examined the specimen given to him by Dr. Chadwick. In connection with this he had looked at the decidua in the cases of extra-uterine pregnancies, which were preserved in the Warren Anatomical Museum, thirteen in number. The cells in this case were as large as those found in the latter cases, and of the same irregular shape. They presented none of the distinctions to which attention has been called by Wyder[2] as existing between the menstrual and puerperal decidua. The orifices of the glands were well marked. As far as this specimen went it would certainly point to the case as one of extra-uterine pregnancy.

DR. F. G. MORRILL, present by invitation, was not sure of the diagnosis in this case between extra-uterine pregnancy and pelvic hæmatocele: he had seen a case of hæmatocele which greatly resembled the one reported, in which the uterus lay in the left inguinal region, displaced there by an effusion: the uterine cavity measured four inches. There were pain, fainting attacks, and hæmorrhage. The mass was aspirated, found to contain blood, and was laid open and the cavity washed out: the patient made a good recovery. Dr. Morrill believed this case might have passed for one of extra-uterine pregnancy, had it not been proved to be otherwise.

DR. BOARDMAN asked for the limit of time when galvanism can be safely applied: he believed it was unsafe in the later months.

DR. JAMES R. CHADWICK, when called in consultation to this case by Dr. West on April 28, 1883, ventured to make the diagnosis of extra-uterine fœtation

[1] See page 243 of this number of the JOURNAL.
[2] Archiv für Gynäkologie, Band xiii., S. i.

on the following grounds: The patient, who had menstruated irregularly every two to three weeks prior to January, had not menstruated from early in January until February 26th, an interval of six to seven weeks, when she had passed decidual membranes; on March 6th she had had an attack of colic and fever simulating localized peritonitis; after a remission of symptoms she had had relapses on March 21st and April 5th; she thought herself pregnant. He found obliquely to the left and behind the uterus a round, elastic, fluctuating body, corresponding in size to the fourth month of pregnancy, crowding the uterus forward and upwards against the pubes and abdominal wall: the tumor was not surrounded by the dense, inelastic induration indicative of a peritoneal effusion. The uterus, both body and cervix, was plainly definable from the tumor, differing in this respect from the condition found with pelvic hæmatocele. He now recognized that he attached too much diagnostic importance to the discharge of decidua, for he had since learned that the patient had passed casts of the uterus several times in the past year; he saw no reason, however, to change his opinion, although he was ready to admit that hæmatocele is not an impossible explanation of the symptoms and condition: this last disease, however, will not explain the great enlargement of the uterus recognized from the beginning and confirmed by a measurement of the cavity in June, when the tumor was subsiding, which still gave a length of four inches. The thin-walled, sausage-shaped cyst felt to the left of the uterus by Dr. Berlin and himself in February, 1884, certainly coincides with the theory of a tubal pregnancy rather than that of hæmatocele.

ON THE USE OF IODOFORM INSUFFLATION WITHIN THE UTERUS IN PUERPERAL SEPTICÆMIA.

DR. BOARDMAN read the paper.[1]

DR. ABBOT asked how much iodoform was used, and how it was applied.

DR. BOARDMAN replied that the powder was applied with an insufflator, which consisted of a small bottle with a metal cap which screwed on, and with suitable rubber tubes for attaching the uterine tube and the insufflating bulb. About two drachms of iodoform were used.

DR. CHADWICK asked if iodoform poisoned.

DR. BOARDMAN replied that there were many reported cases of poisoning; but he believed that a careful analysis of them would show that the symptoms ascribed to iodoform might with equal propriety have been ascribed to the disease for which the iodoform was used. Still there are undoubted cases of poisoning. In a recent French review iodoform was believed to poison by its action on the heart, the poisoning being most likely to occur when the drug was used in large, undrained cavities.

DR. CHADWICK inquired if the results in these cases had been compared with those in which the intra-uterine douche alone had been used.

DR. BOARDMAN said he had observed that when the intra-uterine douche alone was used there were no immediate results; but when the douche was followed with insufflation of iodoform, there was a rapid amelioration of symptoms.

DR. HOMANS said that when iodoform first came into use, it was employed in large amounts and he thought poisoning had resulted therefrom: he did not advise against its use, but thought it should be used with care.

DR. FIFIELD believed that iodoform was a very active poison, affecting the brain and nervous system. In the case of a young lady with syphilitic ulcerations on the wrists and scalp he had used iodoform on the wrists and found it too irritating, hence on the scalp he used it with care, applying not more than one scruple in all: the next day the features, neck, and scalp were much swollen. He believed the use of iodoform was abandoned in New York.

DR. RICHARDSON did not agree with Dr. Boardman in the use of iodoform, and thought the results claimed for that drug were to be ascribed to the preceding intra-uterine injection: he had used iodoform in one case and the patient was poisoned, but recovered when the drug was given up; he then used the insufflation again in the same case and the same symptoms of poisoning recurred.

DR. BOARDMAN wished to differ from Dr. Richardson and did not believe that the symptoms in his case were attributable to the iodoform, but to the chloral which she was taking.

[1] See page 243 of this number of the JOURNAL.

CHICAGO MEDICAL SOCIETY.

D. A. K. STEELE, M. D., PRESIDENT.

STATED meeting of August 18, 1884. The meeting opened with a paper by DR. P. C. JENSEN on

CUTANEOUS THERAPEUTICS,

which created some little discussion.

DR. C. W. EARLE followed with a paper on

INFANT FEEDING AND SUMMER DISEASES OF CHILDREN,

which, being an adjunct to a discussion on cholera of two weeks before, was found interesting. The subject of proprietary or prepared foods, a score or more of which were commented upon as to their merits or demerits for these little people, was thoroughly treated by the writer. We are obliged to abridge the abstract of the paper, as originally prepared by the secretary, but instead give a very brief summary of it, along with the discussion, as found below: —

The conclusions, as summed up, were as follows: —

(1.) The most frequent infantile disease in the city during the summer months is entero-colitis.

(2.) Excluding causes of infant mortality largely beyond our control, improper feeding is one of the chief causes of the great number of deaths among this class.

(3.) Mothers should nurse their children. In lieu of this a wet-nurse should be procured. If this is impossible a mixed diet is preferable, and, lastly, an artificial diet must be resorted to.

(4.) Artificial foods containing considerable caseine are found to be a cause of indigestion and summer diseases.

(5.) In many cases cow's milk diluted with water does not seem to agree with children. Barley water, or rice water, as the diluent, seems to make a more physiological food.

(6.) Condensed milk seems to agree with a considerable number of children, but in many cases a suffi-

cient quantity is not used to nourish a child. Used in proper quantities, and diluted with rice or barley water, it is without doubt one of the best artificial foods.

(7.) Cream, mutton broth, and white of egg are valuable adjuncts to the dietary of infants.

(8.) Whatever the artificial food a child is having, the physician should examine frequently for evidences that it is a proper food as regards quality and quantity. The normal elevation of the fontanelles and increasing weight are among the conditions denoting a satisfactory and favorable nutrition.

DR. J. S. KNOX stated that he judged from the paper that its author had been a bottle-fed baby, as he himself had been, and inquired if this were true? He was answered affirmatively. The speaker, however, differed from the writer somewhat as to the causes of entero-colitis and the other allied summer bowel affections of children. Improper diet is in part a cause, yet the principal causes that produce it arise or are peculiar to the hot weather of summer, heat producing nervous exhaustion in children; they become restless. The anterior fontanelle is a little depressed, and the trouble at first is the child's nervous system is depressed or exhausted. Urgent thirst comes on. Then, too, the child is too heavily clothed; the bottle-fed baby is especially wrapped in flannels, and as a result he becomes more thirsty. The milk and farinaceous foods that are used become sour, and frequently produce fermentation, indigestion, and diarrhœa. A baby from three months old to a child ten years of age may require diffusible stimulants in the morning to stimulate the nerve centres and otherwise during hot weather, such as a little spirits of camphor, aromatic spirit, or valerianate of ammonia, or even whisky toddy. He has occasionally in the summer given his children a toddy before breakfast, and none of them have ever had entero-colitis. For intense thirst give them small amounts of good, pure cold water; feed [illegible] at regular intervals (not too frequently). Farinaceous foods must be prepared fresh only at the time of administering them. Do not give oat meal. If Ridge's food is given it should be prepared with cream. Then try to do without milk. We can give almost any farinaceous gruel or food, and it may be well to substitute a little lime water. Test the excretions, if necessary, and the foods with litmus paper to see if there is an acid reaction. Excessive heat will be likely to produce a heat diarrhœa. When a child is hot give him a cold-water bath; repeat this three or four times a day, on the same principle as for the heat of a typhoid-fever patient. He has frequently seen a baby drop asleep while it was in a cool bath. Entero-colitis in children most likely arises from the heat, such as we have in Chicago during August, which produces exhaustion, fermentation, irritation, interference with nutrition, and catarrhal diarrhœa supervenes.

DR. F. E. WAXHAM differed from both the writer and the gentleman who preceded him as to the causes. The greatest cause is a combination of improper feeding, heat, and impure air. If it were due to improper feeding they would as readily die in the country. If it were due to excessive heat they would die as quickly in the better districts of the city or in the country as in the poor localities. Impure air is mostly prevalent in the poorer localities in houses that are small, containing badly-ventilated rooms that are stifling with heat, where, perhaps, there are present several in a bed, when as likely as not an old pair of boots and filth are seen under the bed, etc. Sudden fluctuation in temperature, combined with other causes, will produce the disease. This is greater in Chicago, New York, Boston, and Omaha, than in New Orleans and San Francisco; the temperature is more uniform in the two latter cities.

In reference to cerebral symptoms (as alluded to in the paper) as a complication, What is the cause, significance, and treatment of such? If a convulsion comes on in a case of entero-colitis, is it due to cerebral disturbance? No, it is a result of pain, and opium and the bromides should be given. Danger of hydrocephalus or meningitis may impend. A blood stasis may form under the finger nails. A serous exudation may have formed in the ventricles of the brain from want of tonicity in the blood-vessels. If so, then we must give quinine and stimulants. It may be a gradual softening of the brain that is coming on. The speaker then cited a typical case of "cholera infantum" that had passed through, as he supposed, these stages of disturbance in the cerebrum corresponding to the appearance described under the finger nails. For two weeks the child's life was despaired of, but it ultimately recovered.

DR. D. M. TUCKER thought children do not require whisky toddy in the morning, before they had been taken ill, as one gentleman had stated. In obstetrics, too, a nurse generally wants to give "toddy" to a baby almost the very first thing she does; this is also equally wrong. We are not usually called to see a baby until it has become pretty sick, very sick. The very first thing we should do is to regulate the diet if necessary, and if the baby has been "filled" with toddy we should order it discontinued.

DR. E. F. GASTON was of the opinion that babies often died of inanition, that the mixed diet and dilution of milk was in many instances overdone, and the little ones often did not get sufficient to sustain them, particularly at a time when their powers of endurance are apt to ebb away: and this is especially true of bottle-fed infants that are a few weeks old.

DR. JOHN BARTLETT thought the field had been well covered by the paper and in the discussion. He would not, therefore, attempt to say much. He thought the sweetness of condensed milk is against using it; that this feature is destructive to its digestion. The causes are several, whether heat, sudden atmospheric changes, irregularity of diet, constitution of a child, fermented foods, etc. All of these combined no one will deny act as causes. He had had good success in these cases from using peptonized food as prepared by J. L. Smith, with the Pancreatic Extract of Fairchild, yet he did not wish to recommend them as being superior to many of the other food preparations.

DR. J. J. M. ANGEAR. According to physiologists children cannot digest starch until there is a saliva, and yet we give starch in the treatment of these cases. His observation as to the causes of these summer troubles gives "over feeding;" and, again, some cow's milk does not agree with children. We wonder why this is so. This was very clearly explained by a number of illustrations, one or two of which may be cited. A baby may be fed on "swill milk," or its equivalent, as that which is obtained from cows fed on slops from distilleries. Where 150 or 200 cows are confined to an acre of ground the mud would become one or two feet deep (he has seen such a place in this city), where the

stench arising from these cow-pens *could be* "*felt* with a stick." The milk such animals gave would present the different colors of a rainbow if allowed to stand for a short time only before using, and when given to a baby it sickened it. In London cans of milk designed for children were sealed by an official placing his official stamp on the cans as being pure milk, or a superior grade of the article. The idea is a valuable one, and should be carried out here; by so doing our little ones would get better milk. Heat also produces the disease by depressing the nerve centres. The heat not only affects the cerebral centres, but the cells of every portion of the body. Heat acts first by stimulating these cells; then they die and contaminate the blood, and this material enters the bowels, and right here the cold-water bath comes in, which we should give the first thing to save the vitality of these cells.

DR. H. J. REYNOLDS regarded the etiology of the disease as heat, imperfect feeding, filth, impure atmosphere, placing a child in a heated room, etc.; besides all these, a peculiar atmospheric condition may produce it where none of the other causes are present. The speaker alluded to electricity as a cause having much to do with producing the disease.

DR. C. E. WEBSTER thought it interesting to note that recent experiments have demonstrated that the saliva of infants is capable of converting starch into sugar as early as the sixth day after birth. The practical value of this discovery is limited, however, by the fact that the saliva is a very small factor in the digestion of starch; the intestinal and pancreatic juices must aid; its ferment is only capable of acting in an alcoholic solution; it is inoperative or wholly destroyed in the stomach, and the digestion of the starch takes place after the passage of the food into the small intestine. These being the facts, it is evident that the matter of the infantile digestion of starch requires further investigation.

DR. G. C. PAOLI thought opium is a very frequent cause of death of little children having enterocolitis or other bowel difficulties; that they should have better diet and fresh air, and, lastly, that more hospitals for them should be erected. With these means we could save them and their lives from the slums and alleys, where the poor live often on old bread, and where garbage and decaying vegetables are to be found.

DR. F. H. MARTIN spoke of the "Sanitarium" recently established at the foot of Twenty-fifth Street on the Lake shore, under the supervision of some Jewish ladies. A few healthy cows are kept there, with clean surroundings, and fed on grass, clean bran, etc. Here twenty five to fifty children are cared for daily and supplied with an abundance of fresh sweet milk and crackers.

This discussion was followed by a paper read by DR. JOHN BARTLETT on

A THEORY OF CHOLERA, OR TWO THEORIES AS TO THE MODE OF ADVANCE OF CHOLERA,

which was very long. The following abstract of it will be read with more satisfaction and greater interest if it be known that the illustrations made use of — the "army worm" and "marsh fungus" — have been carefully studied in the field by the author. Some twenty-four years ago he wrote a long article (the first one ever written on the Army Worm), as may be seen by a perusal of State Entomologist Dr. Smith's New York Report for the year 1861–1862. The author has also had ample experience with the cholera, having passed through two or three epidemics.

While it must be admitted that the knowledge of cholera is very imperfect, it may yet be of interest and profit to frame some theory of the disease which shall conform to every known fact regarding it, and which may offer explanations of the phenomena of the disorder, as satisfactorily as the limited knowledge of such subjects will in the present state of science admit of. Such a theory is of value, if simply as a frame-work which may hold together in an apparently perfect order and relation a large number of fragmentary facts, which might be lost to the mind if allowed to lie detached and disconnected. The writer accordingly presumed to set forth what he conceived to be such a theory of the disease, taking occasion to follow the method of induction, and erecting the theory upon a trestle-work of facts, assumed to be analagous, drawn from other departments of observation. Events are occurring about us similar in many particulars to the rise and spread of epidemic diseases. One of the most striking of these, perhaps, is the prevalence of that plague to vegetation, the army worm. The laws of this pest have something in common with those of cholera. Thus the cause of the army worm is always present in, and indigenous to, certain localities favorable to its development, life, and methods of propagation. Appearing yearly in these habitats, it spreads occasionally, and with some show of periodicity, over extents of territory far beyond its normal limits, and these periodic irruptions frequently cover vast areas of territory, carrying devastation over continents. In this march outward from the nidus of development, pushing onward by some regular yet occasionally interrupted stages, the army worm resembles an epidemic of disease in its mode of approach to a place, its gradual attainment of an acme of destructiveness, and final abatement. Thus the army worm millers, indigenous to certain marshy lands of the South, in the year 1861 sallied from their haunts in illimitable swarms and deposited their eggs in suitable places, and at a suitable period of the growth of early vegetation, in every county from the Gulf to the lakes. These eggs lay dormant until stimulated by the warm weather. Then, apparently, starting from its habitat at the southward, began the northward march of the army worm which overran the country. It was because of the fact of the apparent onward march of the countless hosts of these invaders that they received the suggestive name of "Army Worm." And yet their march was only apparent. They moved only from field to field, as other insects, for the purpose of forage. They advanced northward only as the peach blossom advances northward; their march kept pace with the increment of heat, of the advancing season necessary for the development of the long-deposited egg. The line of their march was an isothermal one. Thus, the worms keeping pace with vegetation, appearing when the winter wheat was "in the milk," advanced toward the north slowly, so that they appeared in Maine two months after they were first seen in Missouri. They had not moved on to other conquests, as people supposed, but the worm, disappearing under the sod, had become a chrysalis, which in a few weeks emitted the miller, which deposited its eggs, and thus completed the cycle of the insect's life. In the above reference to the army worm invasion, it was assumed by some that the whole

field devastated had been run with the germ of the plague the previous season.

Observation of the insect indicated, however, that it passed through its phases within a few weeks, and it is probable that the visitation was not thus sown broadcast and at one time, but that the invasion was by the gradual encroachment of successive "crops" of the worm, so that the insects marching northward into Michigan were not "contemporaries," but the descendants, by several removes, of those which, weeks before, invaded Southern Illinois. Thus a brood of worms, disappearing in the northern counties of Mississippi as chrysalides, were represented, in a few weeks, in Middle Tennessee by millers attracted northward in search of early vegetation suitable as nidi for their eggs. The crop of moths from these eggs would in turn deposit their ova in Kentucky, and so the advance northward would be effected not by the worms, but by that element of the insect floating in the air, and endowed with power of swift flight, and with selective instinct. In regard to the continuance of the recurrence of these insects, it is essential that the several elements find suitable resting surfaces and conditions (of temperature, moisture, etc.), and in the lack of these the element may perish or may remain inactive for an indefinite period, till conditions occur requisite to arouse it to development. Thus in the latitude of St. Louis, with favorable conditions, two or three broods of the worm were hatched in one season, while in Maine a second brood did not appear. Injury to crops wrought by secondary broods in one locality was comparatively limited. The new worms were preyed upon largely by enemies now invading the field, and material suitable for their sustenance was scarce, in good measure exhausted by the depredations of their predecessors. Finally, the miller of the army worm "winters over," and deposits its egg at the appearance of vegetation in the spring. By accident or design the insect, in any of its phases, could be transported to any distance, and as a miller it might be readily carried by the wind. Dr. Koch, the noted microscopical investigator of the causes of disease, believes that he has discovered the actual entity producing the cholera in the "comma bacillus." As yet no more is known of this bacillus than its bare existence. It has a natural history, but the laws of its development and changing growth are yet to be learned. In the absence of such knowledge we may assume that it has certain phases of development, as the army worm has, and that in each one of these it presents different potentialities. In relation to certain fungoid cells, the fact of such phases of existence are ascertained, and from analogy it may be inferred that the "comma bacillus," after a period of active growth, develops into an apparently lifeless-formed material, a crystalline substance, bearing, for illustration, as the writer stated, the same relation to the cell as coral does to the insect which forms it. This crystalline substance is not dead, but living matter, and after a period of passivity, under favoring circumstances, it puts forth buds, which presently burst and emit into surrounding media a protoplasmic fluid, in which, in time, are developed the cells, thus completing the cyclic changes in the life of the plant. The peculiarities of the several elements may be thus stated: The crystalline substance, we may suppose, is in the form of dust, granules, or threads, not an impalpable something, but a material which may be seen by the naked eye, and handled by the fingers. Under the microscope it may be seen to form from an aggregation and concretion of the cells. From it buds, sprouting, emit what may be compared to the contents of an egg, a protoplasm, an apparently homogeneous, aqueous fluid, in which presently begin to appear dim outlines of cells that gradually grow in size and increase indefinitely, not from cell division, but from development of a cell from every atom of the protoplasm. The power of this fluid is only exhausted when its ultimate atom has become a cell. The characters of the protoplasm prior to the development of cells would probably elude all efforts at recognition, so that fluids and tissues of a body containing it might be examined with the highest powers of the microscope without the detection of any organic particles. All parts of the cholera fungus, then, are portable, all are tangible, visible entities, except the infinitely minute atoms of cells in the protoplasm.

The entrance of this fluid into the economy impregnates the system with the ultimate germ of the cells, which under favoring circumstances develops at the expense of the blood, and produces the symptoms known as cholera. The seeds of the disease are brought in the course of travel, to a locality, as crystalline substance, — cholera dust, — or of protoplasm diffused in moisture of the air or water, or in fluids of the human body in the form of cells. Under favoring conditions these elements proceed to perform each its part in nature, so that sooner or later after finding a resting place in a community, they develop protoplasmic fluid, which disseminated by the law of diffusion of fluids in the air and water, or resting as dew upon articles of food, finds its way into the body. The atoms of the poison, infinite in number, and pervading large areas of space, are received into the system of all, as is the pernicious miasm of the marshes. The blood, acting as other fluids have been observed to when impregnated with fungi, resists the changes which it is the destiny of the foreign agents to effect, until the number of the invaders, or some changes in the vitality or chemistry of the impregnated fluid makes longer resistance impossible, and an explosion of the disease like a paroxysm of pernicious fever results. The ejecta from the first cases, filled as they are with cholera cells, find their way generally to a favoring soil, and develop within a few hours succeeding phases of the fungus. Thus crop after crop of cholera atoms are begotten in a prodigiously increasing progression, to extend the area of infection and increase the malignancy of the disease. It may happen that the germs of cholera introduced in a locality find circumstances unfavorable for their development at the time; and although seeds of the disease may be pretty generally sown, they lie dormant for a season. There are certain known facts regarding the cholera, which at least lend plausibility to the theory that the germ may be implanted in a district long in advance of the actual appearance of the disease. Such, certainly, is the case when cholera "winters over," as it is said, lies inactive, it may be, through the fall, winter, and spring, to arise into activity the following summer. It has long been noticed that an epidemic of cholera is often preceded for weeks by the influenza, and a marked and general tendency to diarrhœa. The reasonable assumption, that both the forerunning ailments and succeeding disease were effects of a common cause, would imply the presence of the germ of cholera in a locality long before the actual outbreak of the epidemic.

The march of the pestilence, though generally in the track of travel, is sometimes singularly abnormal as to this law. The cholera sometimes springs up in places far out of the line of apparent exposure. These variations and exceptions to the general law of portability of the disease, suggest a possibility of the truth of the theory, that it may be primarily sown as a temporarily inactive dust as well as implanted as a speedily developing protoplasm. It may be, that in attempting to trace the origin of the disease, by noting in any locality the first case, we err in this, that we compare the course of the epidemic with the line of travel in the presence of the attack, when possibly it is the course of the traveler from the infected district of last year to which attention should be given. The irregularity as to the time and place of appearance may be further referred to the varying soil and temperature of the respective localities considered as developing agents of the deposited germ.

It will be noted that there have been here set forth two theories as to the mode of advance of cholera. The one, that it advances in successive crops from a first, or isolated case; the other, that the seed is sown broadcast over the countries elected for visitation, and that these are developed when and as favorable conditions arise. The number of cycles which the cholera germ may undergo in a season may vary with the locality, temperature, etc., conditions which determine the severity of the epidemic and the length of its stay in a place. Thus, at St. Louis, the number of its cycles might be threefold greater than at Bangor. And a variation in the time of the cycle, also, might influence the rate of advance of the disease.

Changes in the blood, effected by protoplasmic atoms in their act of development into cells, alone produce the cholera. The presence of cells which have already completed their growth, or the material formed from them, cholera dust, does not directly induce disease. Thus, rice-water discharge abounding with comma bacillus may be drunk without injury. The subsequent deposit of these cells in the ejecta of the experimenter may, however, lead to an outbreak of the disease, of which he may prove the first victim. One of the most singular laws of cholera is this, that with rare exceptions it marches *onward*. It remains active in a place a number of weeks and subsides, and the places next attacked are beyond, relatively, the starting point of the district last devastated. In reference to the army worm this is also a fact; and in regard to the march of the insect we can plainly discern the laws. And that, whether it be held that the eggs have been all deposited by the same army of moths or by successive broods of them. In the one case we may suppose the millers, finding the fields of favorable deposit preëmpted, pass onward to unoccupied territory. In the other, because of the devastation made by the preceding generation, the millers of the present must instinctively move onward in search of proper resting places for their eggs.

Means by which man might stamp out or keep out the myriads of army worms which sometimes in a few hours fill to the brim the cordon of ditches plowed about the grain fields, and change in an equally short time flourishing acres of wheat into a "marble ground," can hardly be devised. Plans by which he might unearth and devitalize chrysalides planted under every sod from Georgia to Maine, are difficult to imagine. Methods by which he might successfully contend against the innumerable moths filling the air, might discover and destroy the numberless eggs deposited in every meadow on the continent, are inconceivable.

How infinitely more difficult to avoid or to antagonize are minute cells, the every way and everywhere portable dust, and the invisible, intangible, miasmatic atoms of cholera.

And yet the farmers actually did antagonize their protean plague in all of its phases, and with a fair measure of success. They quarantined against the ever-coming and ever-increasing countless millions of worms. They energetically and persistently worked to keep off from the yet uninvaded fields, by means of a cordon, mechanical and chemical, all possible insects; they plowed under and deeply buried, in order to destroy the chrysalides known to have formed; they attempted to entrap and destroy the millers by cordons of lights, and they burned the grass where the eggs were deposited.

The principles of quarantine against the cholera, suggested by the theory of the disease here presented, may be summed up in the following propositions:—

Elements of the disease known to exist may be isolated or destroyed. Places suitable for the development of the elements may be rendered unsuitable. Ingesta possibly contaminated by the cholera poison may be avoided. Badly infected districts may be evacuated.

According to this theory, during an epidemic the poison lurks in every individual. In the blood of an exposed person are two contending forces, the one the resistance of the vital fluids to the changes attempted to be made by the invading atoms, the other the efforts of the latter to appropriate from the blood materials for their own growth.

One of the first evidences of the yielding of the forces contending for integrity of the blood is loss of serum. The one important event in the chemical change in the blood necessary to give the victory to the ferment (invading atoms) is loss of its serum. Speaking figuratively serum is the essential ally of the blood in its resistance to the invaders. Ejection of ever so little of this tends to render the ejection of other portions easier, and to give the final victory to the poison. Now, while no prophylactic measures are known, it is most fortunate for mankind that remedies are at hand which, if applied in season, may, unless the assault of the ferment be overwhelming, arrest the flow of serum and reënforce the blood in its resistance to the infection. Even when the cholera has held full sway, when it has run its course without interference, it is not necessarily fatal, either because the dose of poison has been insufficient to destroy, or because in some life may continue after the virus has done its worst.

The secondary, reactionary conditions following the collapse known as the typhoid state are complicated phenomena. They are expressions of the efforts of the system in its struggles with the resultants of the cholera paroxysm, rather than a proper stage of the disease. They bear a relation to cholera which may be compared to that which surgical fever bears to injuries which cause it.

This theory of the presence of the germ of disease in the system of all involves the recognition of the principle of acclimatization in this disorder. One may become by gradual inurement habituated to the presence of the virus, and perhaps the majority so inured

are able completely to resist it. As in the yellow fever, however, the acclimation may be speedily lost. Persons whose systems have not thus become acclimated to the poison may be, upon sudden exposure, stricken down with violence.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 11, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

Subscriptions received, and single copies always for sale, by the undersigned, to whom remittances by mail should be sent by money-order, draft, or registered letter. HOUGHTON, MIFFLIN AND COMPANY,
No. 4 PARK STREET, BOSTON, MASS.

ACTINOMYCOSIS IN MAN AND IN ANIMALS.

A PAPER of considerable length and interest upon actinomycosis was contributed to the April number of the *Revue de Médecine* by Dr. Firket, of Liège, under the above title, in which especial attention is given to the bibliography of the subject, and it is pointed out that this disease in man is not of such recent observation as has been generally supposed. Less than two years since many pages of *Virchow's Archiv* were occupied by a bitter controversy between Israel and Ponfick as to which of them rightfully belonged priority of observation and description of actinomycosis in man. Firket insists, apparently with some little justice, that such priority really belongs to Lebert, who, as long ago as 1857, published the first account of human actinomycosis. This may be found in his treatise on Pathological Anatomy,[1] and the radiating fungus which gives its character and name to the affection may be seen figured in Lebert's Atlas.[2] These specimens were found in the "thick, almost gelatinous" contents of an abscess of the thoracic walls of a man aged fifty years, a patient of the famous Louis, who sent the specimen to Lebert for examination in 1848, the man having shown symptoms for four or five months of an affection of the lungs which Louis suspected to be of a cancerous nature. Robin, in his Traité du Microscope, in 1871, recalls Lebert's observations, and gives additional figures of similar radiating masses which he had several times found in the pus of "old, deep abscesses."

Israel first called attention to the subject in 1878 in a memoir read before the Berlin Medical Society, and published in September of that year in *Virchow's Archiv* under the title of "Neue Beobachtungen auf dem Gebiete der Mykosen des Menschen." In this was included, by permission, a case observed by Von Langenbeck in 1845 in connection with a prevertebral abscess, but never before reported. Ponfick's first observations were communicated to the Surgical Congress at Berlin in April, 1879, and published later in the same year in the *Berlin. klin. Wochr.* as a paper under the title of "Eine warscheinlich mykotische Form von Wirbelcaries."

Von Langenbeck certainly, and Lebert apparently, recognized the parasitic character of the maladies presented to them; Israel, whilst regarding his cases as "a special form of pyæmia," realized distinctly the fungoid character of the accompanying growths, and their special parasitic relation to the disorder as a cause, but he neither attempted their precise determination nor recognized the identity of the disease with that previously described by Bollinger in cattle as resulting from this same fungus, named by Harz, a botanist to whom Bollinger referred his specimens, *actinomyces bovis*. This identity was appreciated and established by Ponfick the following year in the memoir previously mentioned, and this seems to be the only real basis to any claim which Ponfick can fairly make to the discovery of human actinomycosis.

Bollinger, who was followed by Ponfick, who has generally been regarded as the first to describe the disease in cattle, and who made his first publication, entitled *Eine neue Piltzrankheit beim Rinde*, in Germany, in 1877, was, moreover, preceded by Rivolta and Perroncito in Italy, where the malady is by no means very rare in cattle, in 1868 and 1875. In Italy the disease is popularly known under the names of *lupia* and *mal del rospo*. In Germany the peasants have various names for it, as Ladendruck, Ladengeschwulst, dicker backen, Krebsbacken, etc., etc. It has been observed, though rarely, in swine and in horses as well as in cattle. For a long time all attempts to inoculate rabbits were unsuccessful, but Israel reports his last efforts with this animal as attended by positive results.

In the United States a few scattered cases of *actinomycosis bovis* have been reported from the West, and one of Eastern origin in the JOURNAL,[3] but the disease as affecting cattle is evidently but little known or not recognized, in this country, and has never been observed in man. Firket puts the number of cases of human actinomycosis reported in Europe up to the date of his publication at twenty-eight, but as no reference is made in his bibliography to five cases occurring in the peritonæum and abdominal organs, reported by Lemann, assistant at the Vienna Pathological Institute, mention of which may be found in the JOURNAL,[4] we are inclined to think he under-states the number. Ponfick collected sixteen cases of his own and others, which were, apparently, all he was acquainted with, and these were incorporated in his monograph entitled *Actinomycose des Menschen, eine neue Infectionskrankheit*, etc., etc., a brochure which appeared in 1882, and summed up the contents of his two previous papers.

The fungous nature of the actinomyces has been well established, but a careful study of the conditions favorable or necessary to their growth, of their development, of their affinities still remains to be made. In the same way their presence in various tissues and

[1] T. i., p. 54.
[2] T. i., pl. ii., Fig. 16.
[3] Vol. cx., p. 532.
[4] Vol. cx., p. 259.

organs of the human system has been perfectly well established, and the various symptoms and effects of their presence upon the organism quite fully described, but little is yet known of their mode of transfer from one victim to another, or of their ways of entering the economy which they attack. Were they found only in superficial situations or in such as communicate readily with the external air the explanation would seem simple, but their discovery in deep tissues and organs, and in places where no communication with the outside exists, makes it much less easy to arrive at a satisfactory solution of this question.

The majority of the cases reported have proved fatal, but there is no doubt that where the affected parts are so situated that the whole of the parasite can be thoroughly removed a cure may be effected. Some observers are disposed to dwell upon the analogies between the processes exhibited by actinomycosis and tuberculosis.

ANTISEPTIC THERAPEUTICS.

At the recent meeting of the Medical Congress at Copenhagen the subject of antiseptic medication was discussed by Ewald, Jaccoud, Bouchard, Grancher, Liebermeister, and others. Ewald was inclined to accord a great value to the discovery by Koch of the bacillus tuberculosis; it had certainly been of great diagnostic importance, and was likely to have an influential bearing on therapeutics. Jaccoud did not understand that Koch's discovery had added anything to the therapeutics of phthisis. If we take account of the fact that the transmissibility of the disease had been established by Villemin, and that the profession was in possession of all the hygienic and medical means of precaution before Koch announced the results of his labors, it will be seen that the discovery of the bacillus has been barren of any useful therapeutical fruits.

Guttman thought this a very narrow and *unmedical* view of the subject. Always when we have had clearer notions of the causation of diseases improvement in therapeutics has followed. We are still, unfortunately, in the experimental period, as far as the treatment of phthisis is concerned, and the discovery of the bacillus is too recent an event to warrant us in denying that it is to have an important influence in the therapeutics of tuberculosis.

Subsequently at this session Bouchard gave an interesting address on Antisepsis in Medicine. The only kind of therapeutics, he said, that is really curative is pathogenic therapeutics, for this aims at the cause. To-day we possess, for a considerable number of infectious diseases, a pathogeny which is positive. A new tentative, then, in the direction of pathogenic therapeutics is warranted, this shall be antiseptic therapeutics.

The value of surgical antisepsis is practically undisputed, but the notion of medical antisepsis has not been so readily entertained. We are told that the infectious element being in the intimate recesses of the organism, it is necessary, in order to reach it, to impregnate the entire organism with the antiseptic substance, which must equally modify the human cells and those of the ferment, and which will kill the patient before killing the microbe.

Bouchard thus states the fallacy of this argument: —

(1.) There are substances innocuous to man which are destructive, if not to microbes in general, to certain microbes. Oxygen, indispensable to man, prevents life in the case of a host of ferments; salts of silver in doses which are without effect in animal organisms arrest the development of an aspergillus.

(2.) There are medical diseases such as dysentery, cholera, and diphtheria, where the infectious agent is, at least for a limited time, on the mucous surfaces and can be reached topically without impregnation of the entire economy by the antiseptic substance.

(3.) Medical antiseptic therapeutics does not propose to kill the microbe (as has been falsely represented), but only to stay its pullulation. In fact, when in infectious diseases the victory is decided in favor of the ferments it is because the latter are incessantly renewed, because new combatants, always more numerous, succeed those that perish in the struggle for existence against the animal cells. In the higher organisms, animal or vegetable, a simple change of environment, of climate, suffices to make them lose their fecundity without compromising their existence. The example of sheep belonging to the department of Beance, which become refractory to charbon when they have been transported for a certain time to Algiers, gives us reason to hope that even slight modifications in the human infected organism may prevent the indefinite multiplication of certain microbes which have invaded it.

Certain clinical facts go to confirm these views. All antithermal medicines are also antiseptic. Quinine, which in typhoid fever may reduce the temperature three degrees and more, does not lower the temperature in a healthy individual. It is even without action in certain fevers, such as attend pneumonia and erysipelas. Quinine would appear to act, then, not so much by its physiological effect on the organism as by being noxious to certain pathogenic microbes. Phenic acid, which is assuredly antithermal, is at the same time a poison to the infectious agent of typhoid fever.

According to Bouchard's statistics, out of one hundred patients cured by the phenic-acid treatment there were ten in whom the disease lasted less than a fortnight. In one case he saw accidental poisoning by the carbolic acid cut short the disease; the temperature fell from 40° C. to 35.7° C., and did not thereafter gain a higher point than 37° C.

All the medicaments whose good effects have been vaunted in typhoid fever are antiseptics.

Clinicians show a certain obstinacy in coming back to the employment of mercury in typhoid. Serres has given the black sulphuret, Becquerel uses the blue ointment by frictions, while Salet administers calomel even to salivation.

The method of Salet has given, as reported, in Bouchard's practice, a mortality of six per cent., and a medium duration of twenty days. All the patients

that have been salivated have recovered, and in these cases the duration of the disease was briefest of all.

The antiseptic treatment of typhoid fever by calomel is realized by giving this mercurial in doses of from one to two centigrammes every hour till the mouth becomes sore. Against the advisability of this method it should be said that convalescence is thereby rendered longer and more painful. Bouchard would not be understood as actually proposing an antiseptic treatment of typhoid fever, at the same time believing that medical antisepsis is theoretically admissible, and in certain cases practically realizable.

It seems highly probable that persevering researches undertaken in this direction will be attended with fruitful results. They ought to be first pursued in the laboratory. A double direction may be given to these researches. In the case of diseases of which the infectious agent has been isolated and cultivated it would be well to test in the culture liquids the sensibility of the microphyte to divers substances called antiseptic. The same medicaments should then be tried on animals which have been inoculated with the microbes of contagious diseases to which they are susceptible. It is by the blood that the medicament must be made to reach the microbes. Intra-venous injections, which, in the present state of science, ought to be interdicted in the human subject, seem to be the preferable means for the introduction of medicaments in animals under experimentation.

Bouchard, as the result of careful experiments undertaken to ascertain the quantities of antiseptic substances which by kilogramme of the weight of the animal will produce death, and the quantity which may be given with safety, has, in respect to many of these substances, arrived at what he calls the therapeutic equivalent of the medicament, that is, the quantity reckoned by kilogramme of the animal, which, when injected into the blood, does not determine toxic phenomena, but beyond which poisoning takes place. He has made this estimate in the case of seventeen antiseptic substances, and has shown that if you associate the proper therapeutic equivalents of several of these medicaments, the antiseptic action of the mixture is augmented more than its toxic action, hence there is an advantage in giving several antiseptic remedies together. In speaking of cases where the infectious element primarily occupies the surface of organs, Bouchard thinks that medical antisepsis has accomplished sufficient to warrant the expectation of greater success in the future.

It has not yet done in diphtheria all that has been expected of it, through lack of processes which enable us to act with sufficient energy on the air passages; it has been applied blindly to cholera, but it has shown itself sovereign in certain arthrites, in certain pleurisies, and in dysentery.

For nine years Bouchard has employed antiseptic medication in the treatment of the complications which arise in the progress of typhoid fever in consequence of intestinal putrefactions. It is relatively easy to introduce into the digestive tube an antiseptic substance, insoluble or but little soluble, so that not being absorbed it may reach the extremity of the intestinal canal; moreover, the medicament not being absorbable cannot produce, even in large doses, a toxic effect in the economy. In having to choose between salicylate of bismuth and iodoform, he has preferred iodoform, which, associated with charcoal, has a wide range of action, and by reason of its extreme division permeates every portion of the mucous membrane, becoming thoroughly mingled with the contents of the intestines.

Sixty centigrammes of iodoform dissolved in one hundred cubic centimetres of sulphuric ether is mixed with one hundred grammes of wood charcoal powder. After evaporation of the ether the iodoform charcoal preparation is suspended in one hundred and eighty grammes of glycerine, and a tablespoonful of this mixture in a half tumblerful of some kind of drink is given every two hours.

For nine years M. Bouchard has been in the habit of giving in typhoid fever wood-charcoal powder internally in quantities of one hundred grammes a day (or a little over three ounces), in ten doses. His object has been not to act upon the typhogenous agent in the blood, nor even to oppose the intestinal putrefactions, so much as to prevent the absorption of the products of these putrefactions by fixing them to the charcoal, the daily dose of which represents a surface of at least sixty square metres. The fecal matters not only lose their fetor, but are absolutely inodorous, and give by filtration a colorless liquid. It is not only the odorous and coloring matters which are fixed by the charcoal, it is also those alkaloids analogous to the ptomaines whose existence in normal fecal matters he has demonstrated since 1882, and which abound in proportion to the activity of the intestinal putrefactions. These alkaloids add their toxic power to that of the other putrid products, and cause even normal fecal matters (and for a stronger reason those of typhoid fever) to become a permanent source of danger, which is only kept in check by the action of the renal emunctory. It is necessary to watch the evacuations to see that the charcoal does not accumulate in the intestines, and to give a purgative when you have left off the treatment.

"In typhoid fever," says Bouchard, "I have noted an extreme rarity of sacral eschars, and remarked that the tongue remains almost always moist. After the employment of simple charcoal I have seen the hospital mortality fall from fifteen to twenty per cent., and after the employment of the iodoform charcoal it has fallen to ten per cent. The same method of intestinal antisepsis I have applied to other diseases which are accompanied with exaggerated fermentation of the digestive tube; in dilatation of the stomach, for example. I have employed it also in cases where the intestinal fermentations were normal, but where oliguria or renal impermeability led me to fear the supervention of those uræmic intoxications which might, I think, be more properly called stercoræmic.

"In conclusion, I will say, that if medical antisepsis has not thus far accomplished all that it promises, it has already realized some therapeutic progress."

MEDICAL NOTES.

— The *New York Medical Journal* of September 6th devotes an editorial to the Boston City Hospital, of which it speaks in an exceedingly complimentary manner. It regrets that the first volume of medical reports has not been followed by others. When one is reminded that its fourth medical report was issued four years ago the *Journal's* regret seems a little ambiguous.

— We learn from our foreign exchanges that Professor Dr. Braun, of Heidelberg, has received a call to Jena as Professor of Surgery, and the Chair of Physiology at Königsberg, rendered vacant by the resignation of Professor v. Wittich, is to be filled up by Professor Hermann, of Zurich. Professor Dr. L. Mauthner is mentioned as the most likely successor to the Chair of Ophthalmology at Vienna, vacant by the death of Professor E. von Jaeger.

— The munificent bequest of $900,000 by the late Sir Erasmus Wilson to the Royal College of Surgeons of England as residuary legatee is by far the largest legacy the college ever received. The next largest was one of $20,000 from the same benefactor. The *Medical Times*, after suggesting various answers to the natural inquiry, "What will they do with it?" adds: "Now is the opportunity to establish a pathological institute on a scale worthy of the scientific reputation of the English school, an institute duly supplied with professors and assistants, and all the appliances required to carry out the complicated procedures of modern pathological research. No institution in the country is better qualified to initiate and direct this advance than the College of Surgeons, with its traditional connection with John Hunter, and its great pathological museum."

— An unusually large number of houses have been ordered vacated by the Board of Health of this city within the past week. In each case the order has been given after persistent refusal on the part of the owner to remedy existing nuisances, consisting in most cases of defective water-closets or offensive privy vaults.

NEW YORK.

— During the last week of August a sailor was found dying in the streets and removed by the police to a station-house under the idea that he was suffering from alcoholic intoxication. On account of the gravity of his condition he was then taken in an ambulance to the Chambers Street Hospital, where the diagnosis of typhoid fever was made. Finally he was transferred to the New York Hospital, where the true nature of the disease from which the man was suffering, yellow fever, was recognized; the diagnosis afterwards being confirmed by an autopsy made by Dr. Peabody, pathologist to the hospital. The following is a partial description of the post-mortem appearances found: The body well nourished but deeply jaundiced. The heart normal in size, but of a bright yellow color, with the valves, endocardium, and aorta deeply jaundiced. The muscular tissue of the heart contained an abundance of fat, all yellow, soft, and pliable. In the lungs were innumerable hæmorrhages, varying in size from a small pea to a chestnut. The spleen was about four times the normal size, dark in color, and somewhat soft. In the stomach the mucous membrane was congested, but not ulcerated, and the organ contained nearly a pint of fluid, largely composed of dark blood. The intestines, which were somewhat congested in the upper portions, contained throughout a large amount of blood; some of which was thick, dark, and tarry in appearance. The liver was normal in size, but the surface was considerably mottled, and presented areas of a brilliant red color, with yellow centres of acini deeply jaundiced. The kidneys were normal in size, but very yellow, with non-adherent capsules, the surface smooth, and the markings distinct. The man is believed to have been taken sick in some sailor's lodging-house, where his associates knew that he was from a yellow-fever port, and to have been put into the streets when well-marked symptoms of the disease presented themselves. His condition was such when he was found that he was unable to give any account of himself.

— The State Board of Pharmacy, created by the last Legislature, was organized at Albany on September 2d, with Dr. A. B. Heusted, of Albany, as president, and E. S. Dawson, of Syracuse, as secretary.

Correspondence.

THE MODERN VIA AD ASTRA.

A MEDICAL FABLE.

Once upon a time a poor but humane physician was riding along a road which led by a dark forest, when he saw by the wayside a sick and miserable dog which had lain down to die. Moved with pity he got down from his carriage, picked up the poor animal tenderly, and gave it some food and drink. Suddenly the dog vanished, and he saw standing before him a beautiful fairy.

"You have saved me from a miserable doom by your compassion," she said. "Command now anything you wish and it shall be yours."

The astonished physician replied, "I am a poor man. I should like to be rich."

The fairy waved her wand, and extended to him a piece of paper and a bottle filled with a dark-colored fluid. "Here," she said, "is a prescription for an Infallible Compound Hair-Restorer. It will never fail, and it has been indorsed by all the leading clergymen on both continents. The world is yours! Do you wish more?"

"I am a quiet man," replied the doctor, "and little known. I should like to be famous."

"You shall be more; you shall be immortal." Waving her wand again, she presented to him a small, dark, and curiously shaped instrument. "See," she exclaimed, "it is a new and 'Unquestionably Perfect Pessary.' It radically restores every malposition. Your name is blown into the side. Generations of suffering women and successful doctors will read, and bless you. I have tried it myself," she added, blushing a little, and vanished.

M. S.

Miscellany.

"ROSE COLD."

DR. MORELL MACKENZIE writes [1] qualifying a remark in one of his lectures that hay fever was unknown in the "good old times," and admitting that though, both in letter and spirit, this statement is perfectly correct, it too much ignores the fact that an individual idiosyncrasy rendering people sensitive to the influence of rose pollen was not very uncommon two hundred or three hundred years ago. As the term "rose cold" has survived in America, says the author, while it is quite unknown here, I think it probable that the complaint may be much more common on the other side of the Atlantic than it is in England; and it is with the view of eliciting some "modern instances" that I venture to bring under the notice of my fellow-workers in the New World some remarkable examples of rose catarrh as related by writers of the sixteenth and seventeenth centuries.

As early as the year 1565 Botallus [2] (known to fame as the discoverer of the *foramen ovale* in the heart) affirmed that he knew persons who held the smell of roses in deadly hatred, because it gave rise to headache, sneezing, and troublesome itching of the nose. Somewhat later Van Helmont [3] (1577–1644) mentions the odor of sweet-smelling substances as causing headache, and in some cases difficulty of breathing. He also gives [4] the case of a canon who was *totâ æstate propemodum asthmaticus, totâque hyeme liber.* It must be allowed, however, that this passage, though suggestive, is not quite conclusive as to the nature of the malady. In 1673 I. N. Binningerus [5] says that he has often heard from James à Brun, a professor of the medical faculty in the University of Basle, that his wife, Ursula Falcisin (a lady, as he is careful to inform us, whose charms were of the "too, too solid" kind, *ampli corporis et carnosi*), suffered from coryza for several weeks every year during the rose season.

A few years later we find Ledelius [6] recounting the case of a merchant of Grünberg who could not smell a rose without immediately suffering from itching, followed by inflammation of the eyes, with profuse lachrymation and headache lasting some days. We come next to a case of especial interest, which was published in 1691 by I. Constant de Rebecque.[7] This passage is important, as conveying the result of an experienced physician's observation of his own symptoms. He tells us that for thirteen years he had been afflicted with coryza during the rose season, which *per totum tempus quo rosæ se mihi offaciendas præbent durat eoque elapso sponte desinet.*

At first he attributed his sufferings to heat, but in the year 1685, when the summer was exceptionally hot, and there were hardly any roses, on account of caterpillars, he was struck by the fact that his annual disorder did not trouble him. The symptoms came on at once, however, after inadvertently plucking a rose toward the end of the season. He concludes that something flows from roses (*e rosis aliquid effluere*) which stings the nose (in his case exceptionally sensitive) and *aculeis quibusdam solutionem continui et si non sensibus obvium excitet.* This observer, therefore, came very near the mark as to the real cause of the disease, to which he applied the term *coryza a rosarum odore.*

An extraordinary case is related by Herlinus [8] (on the authority of Adrian Spigelius, whose name still survives in one of the lobes of the liver) of a Roman cardinal, Oliver Caraffa, who could not bear the smell of roses. This is confirmed from personal knowledge by another writer,[9] who adds that Caraffa was obliged, every year, to shut himself up during the rose season, guards being stationed at all the gates of the palace to stop any visitor who might be wearing or carrying the dreaded flower. It is, of course, possible that in this case the roses may have produced some other affection than rose fever, but as it is distinctly stated that it was the *smell* to which the cardinal objected, we may, I think, fairly conclude that the "sting of the flesh" which tormented him was, in fact, rose pollen.

About the end of the seventeenth century Riedlin [10] relates the case of a merchant with whom he was acquainted, who was afflicted with sneezing and catarrh every year when the roses were in bloom. Riedlin advised his patient to avoid the *cause* of his complaint, a point beyond which we have not even yet advanced.

Heberden's [11] observations make a kind of connecting link between the rose catarrh of the seventeenth century and the hay fever of the nineteenth, for though this physician does not seem to have been at all aware that the complaint had any connection with flowering plants, he mentions casually that five of his patients suffered from catarrh for a month every summer, while another was similarly affected during *the whole of that season.*

In conclusion, Dr. Mackenzie says that he will feel greatly indebted to any American physician who may be able to bring under his notice any well-authenticated case of rose cold.

THE MODE OF ORIGIN OF GENERAL MILIARY TUBERCULOSIS.

THE *Medical News* (July 5, 1884,) remarks editorially that although it has been for some time recognized that a very large number of cases of general miliary tuberculosis are secondary to primary foci, it cannot be said that we have had, until quite recently at least, any accurate information as to the *modus operandi* of such foci.

Buhl early asserted that the general process originated in absorption from a softening mass of cheesy matter, but how this took place, and why in the majority of instances the cheesy focus fails to give origin to secondary miliary tuberculosis, he did not explain. Ponfick's discovery of tuberculosis of the thoracic duct, and Weigert's of tuberculosis of the veins, brought us a step nearer to the solution of the problem. The latter published, in 1879, three cases of acute general

miliary tuberculosis in which he had discovered a large thrombus-shaped tubercular focus in a pulmonary vein, which he regarded as the starting-point of the tuberculosis. In 1882 he reported nine cases of acute general miliary tuberculosis, in seven of which he found tuberculosis of veins, and in two tuberculosis of the thoracic duct. The former appeared as true tubercular infiltrations of the vessel walls, projecting into the interior of the vessel in a thrombus-like or polypoid manner, smooth, except at a single point of ulceration, and centrally cheesy. Upon these observations Weigert based the assertion that *acute general miliary tuberculosis*, in adults at least, *depends upon a tubercular focus either in a vein or the thoracic duct* — ascribing the acute tuberculosis to the sudden introduction of a large quantity of tubercular poison, either from a large focus, or numerous small foci, while that form of general miliary tuberculosis in which only a few nodules are found in separate organs, is ascribed to the disintegration of a small vein-tubercle. So, too, the nodules of varying size and limited number found in the spleen, liver, or other organs, along with pulmonary tuberculosis, he ascribed to the introduction of a small amount of tubercular matter into the blood.

Quite recently, Weichselbaum, in the *Wiener med. Wochenschrift*, No. 12, March 22, has apparently supplied the missing link in the proof of this proposition, by the publication of three cases of acute general miliary tuberculosis in which, associated with tuberculosis of the veins, he found tubercle bacilli in the blood of the patients after death. The first case was that of a young woman of twenty-five, who died of phthisis six days after aborting of a four months fœtus. She had suffered with cough, shortness of breath, and fever for some weeks previous. The autopsy revealed tuberculosis of the uterine veins at the insertion of the placenta, both Fallopian tubes distended with cheesy matter, and their mucous membrane injected, thickened, and infiltrated with small nodules. Some of the cheesy and softened tubercular nodules, as large as a pea and containing nests of closely packed bacilli, protruded into the lumen of the veins and fused with the thrombi found in their interior. Out of twelve slides of blood from a heart-clot — clotted blood was used because of its containing a large proportion of bacilli — four contained the bacilli.

The second case was a man of forty-three, in whom a branch of the pulmonary artery in the right upper lobe contained a polypoid tubercle larger than a bean, ulcerated at one point, cheesy at its centre, and continuous with a large cheesy focus in the same lobe. Preparations from a white thrombus from the left ventricle contained relatively numerous bacilli in groups of from two to six, as did also fresh coagula, and even fluid blood from the femoral vein, although in smaller numbers.

The third case exhibited, besides general miliary tuberculosis, cheesy foci and bronchiectasis, a cheesy abscess about the tendon of the right supinator longus muscle, and chronic tuberculosis of the seminal vesicles, the left vas deferens, the epididymis, and prostate. A cheesy mass surrounded a large vein of the pudendo-vesical plexus, and in one place had perforated the vein. Out of nine preparations made from heart coagula, two contained bacilli.

Weichselbaum believes it a necessary inference from these facts, that in chronic general miliary tuberculosis, that is, the form in which along with pulmonary tuberculosis single nodules of different size and age are found in the liver, spleen, or kidneys, these secondary deposits arise in the same way, even though the bacilli are not found in the blood, since they may easily escape detection when few in number. In support of this view, Weigert has found in two cases of this kind small tubercles in the walls of veins.

COMBINED VERSION IN PLACENTA PRÆVIA.

C. Behm [1] has used combined version in forty cases of placenta prævia, without a single death. This must be regarded as an extraordinarily good result for a condition which ordinarily gives a mortality of forty per cent. Hofmeier has already obtained similar results in the treatment of placenta prævia.

The operation is performed as follows: When dangerous hæmorrhage comes on the vagina should be tamponed until the cervix is closed. This being done, and the woman anæsthetized, the whole hand is introduced into the vagina, and two fingers into the cervix. If the membranes present, the operator endeavors to rupture them with the finger, then draws the presenting part (unless it be the buttocks) to one side, at the same time making pressure from without so as to carry the buttocks down, until he can grasp a foot. This is drawn through the cervix, so that the breech acts as a tampon on the lower segment of the uterus, and the placenta is pressed against the sides of the uterus. In central implantation of the placenta, the finger should be pushed through the centre.

After this version the operator waits for the spontaneous expulsion of the child, or at least complete spontaneous dilatation of the cervix, in order to complete delivery. The duration of labor after version is between one half an hour and eleven hours, the average being one or two hours.

The mortality for the children by this procedure is very great, but the chances for the mother are better. The mortality for the children is, however, no greater than by the old operation.

The causes of the great mortality of the mother under the use of the continuous tamponade is the infection through the blood and other matters adhering to the tampon.

ON THE PROPHYLAXIS AND TREATMENT OF TUBERCULOSIS AND SCROFULOSIS IN CHILDREN.

Tuberculosis is exceedingly common in children, and evidences of it are found in more than half the children dying within the first six months whose bodies are examined. The two objects of prophylaxis are, firstly, to combat the disposition to disease; and, secondly, to ward off infection. The first indication is fulfilled by providing good food, warm clothing, fresh air, a country life, and sea bathing. Infection, that is to say, the bacillus, for the whole paper is written from this stand-point, finds its way either by inhalation, by food, by some mechanical inoculation, or by general diffusion from some previously isolated patch. The commonest path is by inhalation, and accordingly we find the primary disease most frequently in the thoracic

[1] Centralbl. f. d. gesammte. Therap., July, 1884, and Med. News, August 16, 1884.

cavity, the disease commencing in the bronchial glands, in the bronchi, or in the lung itself. To save the child from the introduction of the germ in this way we should instill into those who have charge of it the danger that may arise from sleeping with, kissing, living in a small, confined room with parents or relatives already diseased, and insist upon the necessity of efficient ventilation. Infection by food is not so frequent, but it may be caused by the milk of a diseased cow; boiling the milk removes this danger; and tubercular mothers should not be allowed to nurse their children. Mechanical inoculation may take place from lupus, ulcerating scrofulous glands, or other open scrofulous sores, and possibly, though it has never been proved, from vaccination. Should future investigation prove that the infection of tubercle is spread from these sources, then far greater care than is now taken must be exercised in allowing children suffering from these disorders to associate with the healthy. Swollen scrofulous glands should be removed. The treatment of tubercle and scrofula, as there is no specific remedy known, is comprised in careful management of the symptoms, such as catarrh and diseases of the glands and bones, as they arise, in attention to general hygiene, and in the choice of a suitable climate. — Dr. Förster, *Jahrbuch für Kinderheilkunde*, Band xxi., Heft 3.[1]

IS INTROMISSION NECESSARY TO CONCEPTION?

THIS question has been pretty conclusively answered in the negative, but well-authenticated cases in proof of it are not yet superfluous. Two such are cited in the *Medical Press* (July 16), one reported by Dr. Cass, of Dresden, and a second by Dr. Longshore, in the *Philadelphia Medical and Surgical Reporter* of June 1st. Dr. Cass was called to attend a lady in her third confinement. An examination being made, he found the vaginal canal almost entirely closed, at a point two and one half inches from the orifice, by a firm, unyielding band or curtain. On the pubic side of this curtain there was an opening barely sufficient to permit of the introduction of the top of his little finger. This obstruction was the result of some inflammatory mischief after the birth of her second child, and when she discovered it first she was greatly pleased, as she thought it would prove a sufficient bar to conception. Direct intromission of semen into the womb was evidently impossible; nevertheless, conception had taken place, and the patient's hopes of safety from child-bearing blighted. The membrane was ruptured with the exercise of some force during labor, and delivery safely effected.

Dr. Longshore reports of his case that he was consulted by Mrs. A., a recently married woman, aged nineteen. She had always menstruated regularly and comfortably until after her marriage, which had taken place some three months before coming under his care. Coition was impossible, as the os externum was closed by the hymen, which was very firm and inelastic. It was only after a long and diligent search that a foramen large enough to admit, with difficulty, a No. 11 catheter was found close under the urethra. This condition was undoubtedly congenital in its origin. All her symptoms indicated pregnancy. Dilatation failing, the hymen was divided by means of scalpel and director. Six months afterwards the lady had a normal confinement, from which she made a good recovery. This case proves the possibility of conception under circumstances where it was absolutely necessary for the spermatozoa to travel a long way before impregnation could take place.

[1] Edinburgh Medical Journal, August, 1884.

THE USE AND ABUSE OF THE FORCEPS.

PROFESSOR GOODELL made the following observations in a recent clinical lecture (*Philadelphia Medical Reporter*, June 14th): "Tears of the perinæum will occur whether the physician uses the forceps or not, but in the majority of cases they come from the use of the forceps, or rather from the abuse of the forceps. Let me give a piece of advice to you as young men. When the proper time comes put on the forceps and boldly bring down the head, but when it begins to bulge the perinæum, take off the forceps. I do not think that any of you are competent to deliver the head over the perinæum with forceps. The temptation is to turn the head out too quickly. If you take off the forceps you will rarely have a bad tear, and if it does occur you will not get the blame for it. It is a very rare thing for me to end a labor with the forceps on. When the perinæum begins to bulge, I support the handles to see whether the pains are strong enough to end the labor. If so, I remove the forceps. There is such an abuse of this instrument that I sometimes think that Baudelocque was right when he said that the forceps had done more harm than good. It requires great skill and judgment to end a labor with the forceps. A physician from inexperience, or being demoralized by a long and tedious labor, is liable to use undue violence and deliver the head too quickly, or to make traction in the wrong direction. I have myself torn the perinæum and seen many good physicians do the same. From this experience I should recommend that, unless there be an excellent reason for contrary action, the forceps be taken off when the head reaches the perinæum. Occasionally one blade will catch over an ear and you cannot get it off; but in the majority of cases it can be removed, and that is the proper thing to do."

THE SUPRARENAL CAPSULES.

PROFESSOR TIZZONI has recently[2] performed a number of experiments on rabbits, with the view of clearing up several points in regard to the office of the suprarenal capsules. The usual course was to evacuate the contents of the fibrous capsule of one or both sides. The parenchyma, in the form of a yellowish white pultaceous mass, either escaped into the peritoneal cavity or was altogether removed. Apart from a few exceptional instances of meningeal exudation and softening of the spinal cord, the animals did not appear to suffer in general health by the operation. There was as a rule little traumatic fever and suppuration. Nutrition was rarely impaired; and, in fact, an increase of weight was generally noticed within eight days. The result did not appear to be at all influenced

[2] Gazz. degli Ospitali, June 22d, and London Medical Record, August 15th.

by allowing the parenchyma to remain in the cavity of the peritonæum, where it became absorbed. The interesting point is now to come. After the lapse of some time (length of time not precisely stated) a brown discoloration of the muzzle was observed. Later it extended to the cavity of the mouth and of the nose. It began in the form of small spots, which gradually increased and became blended. This discoloration, it should be noted, never occurred in white rabbits. When only one suprarenal capsule was removed, the pigmentation was exclusively or chiefly on the side operated upon. The altered distribution of pigment was the only effect of the operation, and the group of symptoms that constitute Addison's disease could not be produced experimentally. Touching the histological changes, regeneration was observed in two instances, in each of which the organ had in great part been destroyed. In one of these cases, one hundred and forty-four days after the operation, a suprarenal capsule was found in all respects identical with a normal capsule. In the other case, twenty-six days after the operation, a small nodule of newly formed tissue, consisting of both cortical and medullary substance in process of active development was found. In the connective tissue that surrounded the nodule was a network of the sympathetic, with very fine meshes and large filaments provided with numerous large ganglion cells. The enlargement of the remaining capsule, when only one was removed, was at the expense of the cortical rather than of the medullary substance.

REPORTED MORTALITY FOR THE WEEK ENDING AUGUST 30, 1884.

Deaths reported 2093: under five years of age, 1044; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, fevers, and diarrhœal diseases) 715, diarrhœal diseases 456, consumption 242, lung diseases 121, diphtheria and croup 77, typhoid fever 53, scarlet fever 36, whooping-cough 35, measles 24, malarial fevers 14, cerebro-spinal meningitis 12, puerperal fever five, erysipelas two, typhus fever one. From *scarlet fever*, Boston eight, New York six, St. Louis five, Chicago four, Baltimore, Cincinnati, and New Haven two each, Milwaukee, Providence, Lowell, Lawrence, Springfield, Holyoke, and Salem one each. From *whooping-cough*, New York 14, Boston eight, Chicago five, Baltimore and Milwaukee two each, Cincinnati, Providence, Cambridge, and Salem one each. From *measles*, New York 13, Chicago 10, Fall River one. From *malarial fevers*, New York, Baltimore, and St. Louis four each, Nashville and Springfield one each. From *cerebro-spinal meningitis*, New York five, Lowell three, Chicago, Boston, Lawrence, Springfield, Holyoke, and Salem one each. From *puerperal fever*, Chicago two, New York, Baltimore, and Milwaukee one each. From *erysipela*, New York and Fall River one each.

Cases reported in Boston: scarlet fever 56, typhoid fever 34, and diphtheria 14; in Milwaukee: scarlet fever 21, and diphtheria two.

In 112 cities and towns of Massachusetts, with an estimated population of 1,429,739 (estimated population of the State 1,955,104), the total death-rate for the week was 19.75 against 20.93 and 22.24 for the previous two weeks.

In the 28 greater towns of England and Wales, with an estimated population of 8,620,975, for the week ending August 16th, the death-rate was 24.1. Deaths reported 4052: acute diseases of the respiratory organs (London) 162, diarrhœa 789, measles 103, fever 68, whooping-cough 68, scarlet fever 49, diphtheria 21, small-pox (London nine, Sheffield one) 10. The death-rates ranged from 17.4 in Bristol to 43.3 in Wolverhampton; Birmingham 27.6; Blackburn 28.3; Bradford 25.7; Leeds 29.2; Leicester 28.3; Liverpool 26.7; London 21.2; Manchester 25.6; Nottingham 30.5; Sheffield 27.1. In Edinburgh 15.9; Glasgow 26.0; Dublin 24.2.

For the week ending August 16th, in the Swiss towns there were 42 deaths from diarrhœal diseases, consumption 30, typhoid fever nine, lung diseases eight, scarlet fever two, diphtheria and croup two, small-pox one, whooping-cough one. The death-rates were, at Geneva 9.2; Zurich 11.8; Basle 12.4; Berne 23.3.

The meteorological record for the week ending August 30th, in Boston, was as follows, according to observations furnished by Sergeant O. B. Cole, of the United States Signal Corps: —

Date.	Barometer.	Thermometer.			Relative Humidity.				Direction of Wind.			Velocity of Wind.			State of Weather.[1]			Rainfall.

OBITUARY.

CHARLES WALTER CHAMBERLAIN, M. D., Secretary of the State Board of Health of Connecticut, died at Hartford August 21st, at the age of forty years. Dr. Chamberlain received the degree of A. B. at Brown University, and was graduated in medicine at the College of Physicians and Surgeons of New York in 1871. He was for a number of years examining surgeon to the Pension Bureau, and was well known throughout the country as a distinguished sanitarian. He has from time to time furnished interesting reports to the JOURNAL.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM AUGUST 31, 1884, TO SEPTEMBER 5, 1884.

BYRNE, CHARLES C., major and surgeon. Relieved from duty in Department of California, and to report in person to the commanding general, Department of the Platte, for assignment to duty. S. O. 207, A. G. O., September 3, 1884.

TOWN, F. L., major and surgeon. Relieved from duty in Department of the Columbia, and to report in person to the commanding general, Department of Texas, for assignment to duty. S. O. 207, C. S., A. G. O. Granted leave of absence for twenty-five days. S. O. 127, Department of the Columbia, August 25, 1884.

HAVARD, VALERY, captain and assistant surgeon. Relieved from duty in Department of Texas, and to report in person to the commanding general, Department of the East, for assignment to duty. S. O. 207, C. S., A. G. O.

HALL, WILLIAM R., captain and assistant surgeon. Relieved from duty in Department of Texas, and to report in person, on October 1, 1884, to the superintendent general recruiting service in New York City, for duty at David's Island, N. Y., relieving Assistant Surgeon M. E. Taylor from duty at that station. S. O. 207, C. S., A. G. O.

GIBSON, R. J., first lieutenant and assistant surgeon. Relieved from duty in Department of the Missouri, and to Department of California for duty. S. O. 202, A. G. O., August 28, 1884.

HOPKINS, WILLIAM E., first lieutenant and assistant surgeon. The leave of absence granted him in S. O. 67, August 7, 1884, Department of Arizona, is extended one month. S. O. 204, A. G. O., August 30, 1884.

DIETZ, WILLIAM D., first lieutenant and assistant surgeon. Relieved from duty at the Military Academy, West Point, N. Y., and ordered to the Department of the Missouri for duty. S. O. 202, A. G. O., August 28, 1884.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 6, 1884.

RIXEY, P. M., passed assistant surgeon. From special duty at Washington, D. C., September 8th, and to the Lancaster, European Squadron.

OBERLY, A. S., surgeon. From the Richmond, August 30th, and wait orders.

DICKSON, S. H., passed assistant surgeon. From Asiatic Squadron, July 29th. Sick leave August 30, 1884.

DIED, — In Havilah, Cal., August 31, 1884, Frank Abner Langworthy, M. D., M. M. S. S., aged thirty-four years ten months thirteen days.

BOOKS AND PAMPHLETS RECEIVED. — The Formation of Poisons by Micro-Organisms. A Biological Study of the Germ Theory of Disease. By G. V. Black, M. D., D. D. S. Philadelphia: P. Blakiston, Son & Co. 1884.

Lectures.

TUBERCULOSIS OF THE SEROUS MEMBRANES; DEATH; AUTOPSY.

A CLINICAL LECTURE DELIVERED AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

BY WILLIAM PEPPER, M. D., LL. D.,

Provost of and Professor of Clinical Medicine in the University of Pennsylvania.

GENTLEMEN, — I shall briefly read the history of this young woman, as it is of importance in the diagnosis.

C. K., seventeen years of age, was born in this country. She has lived in a malarial district of Delaware, and has been occupied as a domestic, working hard, and sometimes, especially in summer, much exposed to damp and bad weather. This was particularly so in the summer of 1882. Her father and mother present a history of rheumatism. She had all the ordinary diseases of childhood excepting scarlet fever. She was perfectly strong and hearty until eight months ago, when, after slight exposure, she was taken sick with pains through the body, headache, loss of appetite, feverishness, some sore throat, with a hacking cough, dull pain behind the sternum, and so much shortness of breath that it was impossible for her to lie down for several days. This reads very much like an attack of influenza. The attack came on suddenly, with general soreness, pains through the body, headache, loss of appetite, fever, sore throat, cough, pain behind the sternum, and so much dyspnœa that she could not lie down for several days. This was probably not pneumonia, for we find that in a few days the general symptoms and dyspnœa had disappeared, and that she had returned to her normal condition, with the exception of a little cough, which remained for three months. This was dry and hacking, accompanied with scanty mucous expectoration. This, as I have said, sounds very much like the history of an attack of influenza, followed by a catarrhal condition. Of course it is not impossible that it might have been an attack of rheumatism with some heart complication.

Last May she had an attack of acute articular rheumatism, beginning in the feet and involving almost all the joints in the body, attended with very little fever or sweating, but with pain which was sometimes so severe as to bring on a nervous chill. This rheumatism lasted for two months and a half, and since then she has never felt well. Her appetite has not been good, and after eating she has had distress and a great deal of flatulence. The bowels have been regular. She has steadily lost flesh and strength. About October 1st, nine weeks ago, she noticed that the belly was beginning to swell, and this has continued to increase. At the same time she began to have occasional pain in the hypochondriac region. This was never very continuous or severe, and recently has been even less. Since the first of October she has had to urinate more frequently, and the quantity of urine seems to have been increased.

When admitted she was pale. The pupils were dilated, the right somewhat more than the left, but this may have been a natural peculiarity. The pupils reacted well to light. The tongue was coated, the appetite moderate, and the dyspepsia less marked than it had been, the bowels regular. There were occasional pains through the right chest on taking a long breath. There was a hacking cough, which was worse at night, and was accompanied with a little scanty mucous expectoration. All the time she complained of a sense of shortness of breath. Physical examination of the right side showed no marked signs, but on the left side, in front, from the third rib to the base of the chest, there was flatness on percussion; behind, the whole left side was flat. Over this region there was little vocal fremitus and resonance, and the breath sounds were distant and feeble. The breath sounds were heard a little more distinctly in front, and above the level of flatness a few friction sounds were heard. The area of flatness seemed to change somewhat with change of position. The heart was pushed a little to the left, and on ascultation there was heard a high-pitched, very rough, mitral, systolic murmur. The pulse was dicrotic. The belly was distended, but the veins were not enlarged. As far as could be determined neither the liver or spleen was altered. As I have told you, she passed water too frequently, but it contained no albumen. During November she menstruated and then suffered from some dysmenorrhœa. During all this time she has had some fever, which has ranged between a morning temperature of 99° F. and an evening temperature of over 100° F. or 101° F. On one occasion it was as high as 103.5° F. It presents a considerable diurnal variation of a hectic type. There have been no night sweats. The belly has been diminishing a little in size. She has had a good deal of pain in the right side. About December 4th, four days ago, she began to complain of pain in the head, and she also had some deafness. The fever continued as before.

December 6th the following note is made: "Had no headache this morning, but severe during the night. She had slight wandering delirium at night; no vomiting; bowels regular."

December 7th. More delirious during the night, singing, crying, and laughing, and complaining of severe headache. This passed off in the morning. The dullness of hearing increased. During the day the mind was perfectly clear."

When admitted she was put on Basham's mixture with alkaline diuretics. When the fever continued full doses of quinia were given for a number of days, eighteen grains per day being given with solution of acetate of ammonia. This proving unavailing we returned to Basham's mixture and cod-liver oil. As you see, the treatment has consisted of careful attention to diet and in the use of diuretic iron mixture and alkaline diuretics to carry off the pleural and peritoneal effusions, and more recently in the use of bromide of potassium to control the cerebral symptoms which have been mentioned.

This case has given a great deal of anxiety, largely on account of the difficulty in diagnosis, as you see the morbid elements which are present are numerous. You also see why it was that I referred to the possibility of the first attack being one of rheumatism. Her family presents a strong tendency to rheumatism, and in May, five months after the first attack, she had a severe attack of ordinary acute articular rheumatism, which has left behind it mitral regurgitation, as shown by a strong, low-pitched, rough mitral, systolic murmur. In addition, we have coming on without any œdema, internal dropsies, right pleural effusion and ascites, and this long-continued febrile action, and more recently these cerebral symptoms.

In trying to arrive at a correct understanding of the nature of this case the following thoughts have occurred to me. Is this a case of chronic malaria, complicated with sub-acute rheumatism and great anæmia leading to these internal effusions? Is it a case of protracted rheumatic fever with ulcerative endocarditis, with the endocarditis progressing, keeping up the irregular fever with irritation of the serous membranes causing effusion, as will sometimes occur in these long-continued cases of septic rheumatic trouble? Not rarely in such cases will you find nervous symptoms appearing in their course. Is it a case of rheumatic trouble with serous tuberculosis, causing tubercular pleurisy and peritonitis and recently tubercular meningitis? It is very difficult to answer these questions.

You will observe from the history that all renal complications must be left out of consideration. The urine has always been normal. There is no question as to the lesion of the heart. The only question is whether or not it existed before the last attack.

The effusion on the right side interfered greatly with determination of the condition of the lung. Now that this is somewhat removed we may be able to obtain better results. On auscultation, I detect on the left side, in front, below the outside of the cardiac region, sharp, crackling, friction sounds. Over the lower part of the right chest in front, where it is still comparatively dull and slightly tender, the respiratory murmur is weak, but there are no râles or friction sounds. Posteriorly the respiratory murmur is feeble, distant, and blowing. After coughing, I hear a few deep-seated, coarse, snoring râles. The right pleura is thickened by exudation, compressing the lung. This exudation is plastic. There is a condition of chronic pleurisy of the right side, and there is a small patch of dry pleurisy on the left side.

Let us now turn to the abdomen. The distention has been somewhat reduced, but fluctuation is still very distinct. The abdomen is very tender on pressure; I think that there can be little doubt that this effusion is dependent on peritonitis. This is not a passive effusion. There is no affection of the kidneys nor of the liver. The liver is not enlarged, and there is no jaundice. There has been pain which has been referred to the region of the liver and to the right shoulder as though the capsule were involved, but that would not be improbable on the supposition that there was peritonitis. The heart lesion cannot explain the ascites. There is no œdema of the feet or hands, and in cardiac dropsy internal effusion, and especially ascites, does not occur unless the œdema is very great. The degree of the heart trouble is not very serious, but its quality may be. To this I shall refer in a minute. I think that we must regard the peritoneal and pleural effusions as irritative and the result of inflammation of the membranes.

I feel less certain in regard to the nature of the cerebral symptoms, and before expressing any opinion I shall wait until I have obtained the result of the ophthalmoscopic examination, which I consider necessary. At present her condition is a typhoid one, and it would not be unnatural that, after such an illness, cerebral symptoms of a low, adynamic, typhoid type should develop. I should warn you against concluding, even in the presence of the most threatening symptoms, that organic disease of the membranes had developed. We have in the ophthalmoscope a most important aid in the diagnosis of such cases as this, and one which should always be employed. In meningitis, especially of the tubercular variety, retinal changes are apt to develop, which are sometimes so characteristic as to enable the diagnosis to be positively made at a glance. If the symptoms are due to the typhoid condition the results of the examination will be negative.

What other condition than tubercular peritonitis and pleurisy could we have running a slow course and engendering a low typhoid condition with cerebral symptoms the result of the adynamic condition or of meningeal irritation? Another explanation might be found in a septic state of the system from ulcerative endocarditis, a rare condition, but one which is met from time to time, and presents such peculiar symptoms that it requires careful study before it is recognized. Ulcerative endocarditis runs the course of chronic pyæmia. The detritus from the degenerating endocardium, which presents little ulcers which sometimes perforate the valve and sometimes form little masses on the surface of the valve, is thrown into the blood, and passing through the system gives rise to numerous minute septic emboli. Septic foci are established in the spleen, kidneys, and lungs, and with this there is pyæmic fever of a hectic type with marked diurnal variations in temperature, sometimes with distinct sweating, but not, as a rule, with the drenching sweats which attend the rapid development of surgical pyæmia. This runs a slow and chronic course. It is attended with various secondary lesions. Sub-acute inflammation of the serous membranes is not rarely met with. Here we have a girl who has had an attack of a vague character and a second attack of distinct rheumatism, who now has marked cardiac disease. There is no history of tubercular disease in her family. But this is not essential. The association of tuberculosis with cardiac disease is not frequently met with, but still it may occur.

In either case the prognosis is most grave. If there were lesions in the lung there would be no doubt as to the diagnosis. As it is, I must say that my own judgment is in favor of the view that there is tuberculosis of the serous membranes. The ophthalmoscopic examination will be of great importance. I shall have it made and give you the results next week.

The diagnosis rests between these two rare and grave conditions, and on the whole I think that the balance of evidence is in favor of the view that there was an old mitral lesion which was increased by the last attack, and which is now associated with tuberculosis of the serous membranes.

The treatment has been simply a supporting and apyretic one. We cannot use specific remedies against either of these conditions. I do not think that we can do better than continue the careful regulation of diet and the tonic and deobstruent treatment which has been pursued, and the use of bromide when called for to allay the excitement.

(The ophthalmoscopic examination showed indications of intra-cranial trouble. Descending neuritis with œdema of the retina was found, but no retinal tubercles were detected.)

December 22d Dr. Pepper again referred to this case as follows: —

The young girl, C. K., whom you saw two weeks ago, gradually failed and died on December 16th. The autopsy was made by Dr. Formad, who gives us the following report: "A tall, well-shaped girl, not markedly

emaciated, but very anæmic in appearance. The abdomen greatly distended with gas and ascitic liquid. Old adhesions obliterated entirely the right pleural cavity. There was no liquid effusion. The pericardium was normal, but contained about five ounces of clear fluid. There was slight thickening of the mitral valve and shortening of the cordæ tendinæ, allowing regurgitation. The right lung was collapsed, the pleura much thickened by plastic exudation and the seat of tuberculous formation. A moderate amount of gray miliary tubercles were found scattered through the substance of the right lung. The left lung also contained a number of gray tubercles, but not as many as the right lung, and without plastic pleurisy.

"The peritoneal cavity contained two quarts of straw-colored liquid. All parts of the peritonæum presented gray tubercles. There were old adhesions in many parts, particularly in the lumbar region around the mesentery and pancreas, matting together the viscera. This new-formed mass was crowded with tubercles. The lymphatic glands were moderately enlarged but not cheesy.

"The liver was normal, its capsule studded with tubercles, but no tubercles were discovered in the parenchyma. The spleen was covered with tubercles, but none inside. The kidneys showed signs of an early stage of chronic parenchymatous nephritis, but this certainly had not advanced far enough to cause alteration of the urine, for this was carefully examined a number of times with negative results.

"The brain was normal, only a few gray tubercles being found in the Sylvian fissure. There was about sixteen ounces of serous effusion."

CONCERNING THE ÆTIOLOGY AND PATHOLOGY OF HYDRAMNIOS.[1]

BY CHARLES M. GREEN, M. D.

Since writing the paper[2] which I read to this Society in February last, wherein I sought to formulate the present knowledge of the origin and pathology of hydramnios, I have met with another contribution to our knowledge of the subject by Dr. Nieberding of Würzburg, who has recently observed and carefully recorded[3] two cases.

In the winter of 1883 Nieberding observed hydramnios in a case of twins from one ovum which he reported in a monograph entitled Beitrag zur Kenntniss der Genese des Hydramnion. In this case not only was one twin more developed than the other; but there was a considerable effusion in its cavities and great œdema of its whole body: hydramnion existed in only one of the amniotic sacs, and that one contained the larger fœtus. The placenta was single, and that part of it which nourished the larger fœtus was of greater size and was in a high degree infiltrated with serum. The pregnancy terminated at the end of the sixth month, and while the smaller fœtus showed no anomaly except a certain hyperæmia, examination of the larger fœtus disclosed a considerable hypertrophy of the heart and kidneys, and great infiltration of all the organs with red and white blood-corpuscles. The hypertrophy of the heart was chiefly of the left side.

If now the question is asked, says Nieberding, to what causes are to be attributed the pathological increase of the liquor amnii of one sac and the dropsy of the fœtus contained in this sac, it must be answered that it is possible that an increased transudation from the maternal blood-vessels might have been the causal factor. Since, however, originally the size and presumably the permeability of both embryos were approximately the same, there is no reason why one sac should be thus filled and not the other. The idea that the vasa propria of one part of the placenta contribute conspicuously to increase the amount of the liquor amnii over and above the same vessels of the other part Nieberding says must be abandoned, since it was established by microscopical examination in this case that the chorionic capillaries were equally developed on both parts of the placenta and that those of the hydramnic part, instead of remaining patent longer than usual, were in great part obliterated. Nieberding therefore believes that the cause of the hydramnic condition of one sac in conjunction with dropsy of the contained fœtus must be sought in the circulatory conditions of this fœtus; and this belief is warranted by the pathological appearances in the present case, which were as follows: hypertrophy of the heart, especially of the left side; great enlargement of the kidneys with dilatation of the pelves, filling of the glomeruli with red and white blood-corpuscles, and the presence of moderate blood-extravasations; considerable dilatation of the ureters and of the bladder, although the urethra was entirely permeable. These pathological changes must have their causes, and these causes were traced by Nieberding to a premature obliteration of the ductus arteriosus. The early closure of this duct must surely entail great changes in the fœtal circulation: more blood must perforce enter the lungs; at the same time the blood-tension in the right ventricle must be greatly increased. On account of this tension not only would there result a backing-up in the whole venous circulation; but at the same time a greater quantity of blood would be forced through the foramen ovale into the left side of the heart, which on account of the greater demands thus made upon it to force on the increased amount of blood would hypertrophy and thus increase the tension in the arterial system. Herein, according to Nieberding, lies the explanation of all the anomalies of the affected ovisac and its contents: while the fœtal œdema and dropsy were caused by the venous backing-up, which through the umbilical veins occasioned also the serous infiltration of the placenta, the increased arterial pressure resulted in an increased filtration by the kidneys, an increased diuresis: this increased amount of urine must have been evacuated from time to time, else there would have been found an enormous distention of the bladder; and this polyuria, according to Nieberding's firm conviction, must have had the most conspicuous share in the dropsical distention of one ovisac, while, on the contrary, the weakened heart of the other twin caused a lower arterial tension, a smaller secretion of urine and a minimum amount of fluid in its containing amnion.

Quite recently Nieberding has had a second instance of hydramnios in a case of single fœtation. A previously healthy secundipara, thirty-two years of age, whose first pregnancy and labor had pursued a normal

[1] Read before the Obstetrical Society of Boston, May 10, 1884.
[2] See vol. cxi., No. 6, page 121, of this Journal.
[3] Allgemeine Wiener Medizinische Zeitung, March 11, 1884.

course, and who was in the sixth month of her second pregnancy, sought advice on account of uterine hæmorrhage. Examination showed that for the time of pregnancy the abdomen was much distended, and that the position of the fundus uteri corresponded to the end of pregnancy. The fœtus was living, but was very small and very freely movable in the great amount of liquor amnii. The hæmorrhage ceased under the influence of rest and opiates. Two weeks later Nieberding found that the circumference of the abdomen had rapidly increased to such an extent that the woman was greatly distressed and had lost much strength. At the same time there was marked œdema of the legs and also of the vulva, indeed each of the labia majora had swollen to the size of a man's two fists: the fœtal heart could no longer be heard. On account of these symptoms Nieberding induced labor on the following day by puncturing the membranes: an enormous quantity of liquor amnii escaped, sufficient to fill once and a half times a large water pitcher.

The fœtus, of female sex, twenty-four hours dead before delivery, was well developed and corresponded to the beginning of the seventh month of pregnancy. On opening the abdomen the bladder showed itself greatly distended with urine and extended as high as the navel: the urethra was completely passable with a small catheter. The heart was very large and hypertrophied in its left half: it was larger than the heart of the pathological twin of the first case: the muscle was healthy and the valves normal. In the lungs, as in the first case, was observed, besides a considerable blood-cell infiltration, a large increase in calibre of the arteries with a well marked thickening of the vessel-walls. The liver was large and infiltrated with red and white corpuscles in the vicinity of the vessels. The kidneys were enlarged, and there was dilatation of the pelves and calices; the glomeruli were filled with blood-cells, and there was blood-cell infiltration of the parenchyma. The placenta was large and very œdematous and studded with a great number of large and small cysts from the size of a hazel-nut to that of a hen's egg, which were seated more or less in the vicinity of the chorionic covering of the placenta. The cord was inserted near the edge. Countless old and new blood clots, some of considerable size, were found as well directly under the chorion as on the uterine surfaces of the cotyledons. Under the microscope was observed, as in the first case, frequent obliteration of the vessels with greatly hypertrophied vessel-walls, which gave the impression of fibroid growths, which were perforated sometimes by one, but commonly by two very small vessel-openings. The cysts hung, as it were, on the vessels which were in intimate connection with the cyst-wall. Sections of these vessels at the seat of their passage into the cysts showed that an artery and a vein lay together: the artery appeared obliterated before its insertion into the cyst-wall, in order to develop itself as a cyst. The vein, much dilated and drawn out in breadth, surrounded the obliterated artery in a half circle, so as to lie smoothly over the cyst-wall. In the cyst-fluid were found countless, more or less altered red and white blood corpuscles. Finally the vasa propria of Jungbluth were seen traversing the chorion, not in great number, but often beautifully injected.

On laying open the ductus arteriosus lengthwise, Nieberding found its lumen filled with crumbling masses which reduced considerably the calibre of the duct. Microscopic examination showed these masses to be proliferations of the muscular coat and intima, as in the first case. He therefore has no hesitation in considering the premature obliteration of the arterial duct as the primary anomaly on which the circulatory disturbances of the fœtus and the other pathological changes depend. He also believes that the great increase in the amount of liquor amnii arose from the extraordinary increase of the secreted urine, without, however, entirely denying that other factors may have had some share in the increase. Nieberding adds that it now remains for him to examine the arterial duct of fœtuses from the same period of pregnancy where hydramnios does not exist, in order to prove whether perhaps the physiological obliteration of the duct at full term can occur in certain cases without being accompanied by so considerable anomalies of the ovum.

It does not seem to the writer, however, that Nieberding's cases and conclusions, interesting as they are, change materially the already accepted views on the pathology of hydramnios. Any pathological change in the fœtus, in the cord or placenta which disturbs the circulation so as to cause venous stasis or increased arterial tension would naturally result in dropsical effusions or increased filtration of urine: the fœtal skin and kidneys, and perhaps the umbilical cord and the chorionic vasa propria, would thus naturally contribute to increase the amount of liquor amnii. Whether the first disturbing cause is found to be in the heart, in the liver, in the kidneys, or in the placental circulation, the final result would doubtless be the same.

CRANIAL BONES OF A FŒTUS REMOVED FROM THE RECTUM.[1]

BY O. W. DOE, M. D.

E. W., colored, widow, fifty-two years of age, entered the City Hospital on April 8th last, complaining only of diarrhœa. Her discharges averaged about seven in number daily and were very thin and often slightly bloody. Under the use of astringents she had but one daily, and after having been kept in bed for two weeks she was allowed to sit up. On doing so, she stated that a very full watery discharge from the rectum took place, and she had no voluntary control of the sphincter. The nurse was directed to give a laudanum injection, but found it impossible to introduce the syringe, as it seemed to impinge against a hard substance just inside the anus. My assistant, Dr. Welch, was called, and found that the obstruction was caused by a collection of small bones, one of which was removed and found to be the left temporal bone of a fœtus. By questioning her closely the following history was obtained, though she seemed somewhat unreliable in respect to dates: —

She had borne three children, the last thirteen years ago: her labors were not difficult. Ten years ago she had a miscarriage when about four months pregnant; but, as the only thing that came away resembled a piece of liver, she was not sure that it was a miscarriage. Since then her catamenia have been regular, until their cessation five years ago. About six months ago something rather hard, about the size of an orange, passed through the rectum. Since then she has had a diarrhœa, the discharges at first being accompanied

[1] Read before the Obstetrical Society of Boston, May 10, 1884.

with pain and containing crumbly matter. The dejections during the last two months have occurred sometimes as often as every fifteen minutes, and frequently have taken place involuntarily during sleep: they were very much less frequent when the patient was in bed. During the past two months there has been considerable abdominal pain and rectal pain, which would be relieved by defecation. The day before entering the hospital she passed two pieces of bone from the rectum; one resembling half a wish-bone; and the other, the upper part of a chicken's leg. When the patient first entered the hospital examination of the abdomen revealed nothing abnormal. There was some emaciation, but not as much as one should expect to arise from a diarrhœa of six months' duration. On the day when she had the large involuntary discharge on sitting up there were noticed hard masses in the left inguinal region, which moved under the fingers, and also a large tumor above the pubes, which proved to be an over-distended bladder. The patient then stated that she had passed urine only at intervals of three days during the past three months, feeling no inclination to pass it oftener. In removing the bones four of the largest ones were found in close juxtaposition about an inch inside of the anus: they were quite freely movable, and, as the sphincter very readily dilated, they were removed with but little difficulty. Three fingers could be easily introduced into the rectum, and but little, if any, laceration of the sphincter resulted. After removal of the bones near the anus another collection was found closely imbedded together, directly underneath the promontory of the sacrum. There was much more difficulty in removing them, especially the first one, and in their removal a considerable amount of a thick cheesy deposit was noticed. The fingers could not recognize any distinct rectum, but high up seemed to enter a large sac containing the bones, the walls of which seemed to be defined by a thick cretaceous deposit.

The bones were removed fifteen days ago, and since then the patient has had no unfavorable symptom. The temperature was 100° F. the day following the operation, and since then normal. She is now sitting up and has on an average two dejections daily, lately well formed. The sphincter shows no signs of any laceration having been produced; but the rectum is still very capacious and not easily defined, the finger apparently entering a large cavity with soft, cheesy-like walls.

PENETRATING GUN-SHOT WOUND OF THE NECK.

BY EDWARD O. OTIS, M. D.

ON the morning of April 9th, between nine and half past, a stout, fleshy man, about forty or forty-five years old, was riding along a quiet village street. Passing by a house he felt something like the sting of a wasp on the right side of his neck. He fell partially over on his side, and attempted to raise his right arm to beckon to some one who was passing. He found his arm powerless, but five minutes after, he said, it regained its power. He realized that he was shot, and so stated to the one who came to his assistance. Aphonia came on immediately. He was taken to his home in partial shock, from which he was said to have rallied in about an hour. There was much difficulty in breathing.

I saw him in consultation the night of the next day, about thirty-six hours after the accident. He was partially dressed, and sitting in a chair. His respiration was about normal; pulse was 120; and temperature 101° F. He had been coughing much since the accident, with the expectoration of considerable mucus, but no blood. There was no pain, except on swallowing, which was difficult.

On examination I found a rather ragged, circular wound, about five sixteenths of an inch in diameter, on the right side of the neck, which was short and thick, two inches, in a vertical line, below the lobe of the ear, the head being pretty well extended. The edges of the wound were dirty, and I thought I detected a few linen fibres, the bullet having gone through his coat and linen collars. It was moderately swollen and tender about the wound. On the opposite side of the neck, four and a quarter inches below the lobe of the ear, and two inches in front of a vertical line, was a cut about half an inch long, which the attending physician had made in extracting the bullet, which, he said, was just beneath the skin. On the linen collar was a very little blood, which was about all the external hæmorrhage there was at the wound of entrance.

I was told that there had been considerable discharge from the wound of entrance, which, on examination, was very much in appearance like the gruel he was being fed with. I also noticed bubbles of air, mixed with the discharge, after coughing. On coloring some milk with tincture lavender, which happened to be near, and asking him to swallow it, I detected the colored fluid oozing from the wound. No fluid at all appeared from the wound of exit, nor was there much of any swelling or tenderness on that side of the neck. On examining the interior of the throat as well as I could at night, and not under the most favorable circumstances, I found considerable congestion and much mucus. The lungs were clear. The first question to decide was the course of the bullet, and what structures had been injured. The direction of the bullet from the positions of the wounds of entrance and exit must have been from above downward, and from behind forward. As it entered it must have penetrated the sterno-cleido-mastoid muscle or grazed its posterior border, passed through the other muscles and tissues between it and the pharynx, penetrated and passed through the pharynx, then made a detour about the great vessels of the left side, finally stopping directly over them and under the skin. This deflection of the bullet was more to be expected at this place than at any other, because the bullet's velocity was nearly spent. A straight line drawn from the point of entrance to that of exit would strike the vessels of the left side.

Let us now see how the accident occurred.

A student left lying in his room a revolver of 32 calibre, known as the "Excelsior" pattern, having five chambers. Two of these chambers, adjacent to each other, were loaded. A fellow-student coming in, and seeing only the unloaded chambers, supposed they were all so, and so amused himself by snapping the revolver. The first time he pointed it towards his foot, and the hammer came down upon an empty chamber. The next time he aimlessly pointed it out of the window, and the hammer struck one of the two cartridges. The bullet went through a window pane only an inch inside of the sash. Directly in front of the window was an elm tree of moderate size, and

perhaps five or six feet distant from the house. The bullet must have just grazed this tree, but it was impossible to discover any trace on the rough, broken bark. A vehicle passes any given point on that street on an average of once in ten minutes, I should think. Just at this time a vehicle did happen to be going by. From the head of the horse to the end of the wagon is quite a distance. Any part of this distance might have been in front of the bullet at the exact time of its discharge, and the chances were many to few against the man's neck being in front. It was in this case. Any part of the neck might have been in the bullet's track. The chances were infinitely few that just the point between the spinal cord behind and the great vessels in front should be the safest place to tap the pharynx from the side. Just that point did happen to confront the bullet.

Let us sum up the immense preponderance of the chances against the bullet's causing the accident it did or, indeed, any accident. First, it struck only one inch beyond the window-sash. Second, a tree was directly in front of the window. Third, a vehicle passes the window only about once in ten minutes. Fourth, the thickness of a man's neck is only a very small part of the line drawn from the head of the horse to the end of the wagon. Fifth, the time the whole of a vehicle is passing a given point is very short; very much shorter is the time a man's neck is passing that point. Sixth, the safe track for a bullet through a man's neck and pharynx is extremely limited. Lastly, there were only two out of the five chambers of the revolver loaded. The hammer had already descended upon one empty chamber, so that there remained two loaded and two empty chambers, making the chances for and against hitting a cartridge just equal.

The bullet went out of the window at a vertical distance of about twelve feet from the ground, and the man's neck was about five or six feet from the ground.

One side of the bullet was turned up while the other side was smooth, and in crevices of the turned-up side were black particles, which, under the microscope, proved to be dark fibres, probably from the coat collar, which was penetrated. The bits of coat and linen collar cut out by the bullet were not accounted for at the time of the accident; later, as we shall see, they appeared.

The treatment advised was of the simplest: surrounding the wound with some light antiseptic material, nourishing the patient partially by the rectum or by a stomach tube, interdicting speaking, a moderate opiate, quiet and good air, careful watching.

I was summoned again two days later to see the patient, and from that time until convalescence, some four weeks later, saw him frequently. A large suppurating cavity formed at the wound of entrance, connecting with the interior of the throat by an upward circuitous passage. Two counter-openings were made at the most dependent portions, one directly below the bullet hole, and another below and in front. A drainage tube was passed from the bullet hole to the counter-opening below. A day or two later this whole tract was cut up. The wound was thoroughly syringed out each day, and an antiseptic dressing applied, — iodoform, carbolic gauze, oakum, etc. At first a carbolic-acid solution was used to irrigate the wound, but as at every washing some of the liquid entered the throat it was thought that the acid increased the irritation there, and its use was abandoned. Alcohol and water and a solution of chloride of zinc were tried, and finally a borax solution was relied upon as being unirritating to the throat. For two or three days considerable sloughing ensued, with much discharge, and a very foul odor. The temperature oscillated between 100.5° F. and 102° F., and the pulse from 116 to 120. After the tenth day the sloughing ceased, and the temperature fell nearly to normal. From the fifth to the twenty-sixth day (twenty-one days) he was fed entirely by the rectum and stomach tube. On the twenty-sixth day the passage from the wound to the throat was apparently closed, and he was allowed to eat the natural way, which he continued to do from that time forward. There was great irritability of the throat and much accumulation of mucus, often purulent, from discharge from the external wound. On the sixteenth day of the accident a large abscess at the point of exit opened, and the lost bits of the linen and coat collars were extracted, having been carried through the neck by the bullet in its wandering; a most fortunate circumstance, that they were not left in the deep portions of the neck to cause grave trouble. This abscess healed in a few days. On the thirty-second day the external wound was healed, with the exception of a small granulating point. The patient was still aphonic, however, and on laryngoscopic examination the pharynx and larynx were found thickened and congested, particularly the ventricular bands. He also complained of lack of power in the right arm, and his head was deflected a little to the right side. Both aphonia and torticollis, more or less permanent, occur in many cases of injury of this kind.

The case is one of interest in several ways: —

First, consider the detour the bullet must have made to avoid the great vessels on the left side of the neck, for it lay beneath the skin immediately over them. The escape of the great vessels in penetrating gun-shot wounds of the neck is noted with wonder in treatises on military surgery. "Few[1] writers on military surgery have failed to remark on the curious manner in which missiles elude the great vessels of the neck, though passing, apparently, in their immediate track. Dr. Williamson, Sixty-Fourth British Regiment, suggests an explanation of this phenomenon. He says: 'It is remarkable that the large arteries and veins in the neck should escape injury so frequently in gun-shot wounds. This may in some measure be accounted for by the structures in this region being so loose and movable that they yield or recede before any projectile.'"

Second, consider the risks to be feared during the first ten days: sloughing and invasion of the great vessels; deep suppuration and descent of pus into the chest; trouble from the bits of foreign substance, the place of lodgment of which was unknown; acute pharyngitis and laryngitis, causing grave disturbance in respiration; pyæmia and erysipelas.

Third, the difficulty of treatment from the location of the wound and the parts involved. Whatever fluid was used to irrigate the external wound entered the throat, so that care had to be used in the selection of the antiseptic. Then there was the difficulty of feeding. A throat already inflamed had to be continually rasped by the passage of a stomach tube.

Hamilton, in his Military Surgery, says that when

[1] Medical and Surgical History of the War of the Rebellion, Part I., Surg. Vol., p. 412.

the œsophagus is wounded, a similar condition to that of this case, the first duty of the surgeon is to pass a stomach tube, and permit it to *remain*. In this case, at least, I think this procedure would have increased the irritation, and added to the discomfort of the patient.

Fourth, as I have already shown the remarkable combination of chances which produced the accident, the unfortunate cause of it would most assuredly re-echo the words of Shakespeare's Cloten, —

"Was there ever man had such luck."

REPORT ON NERVOUS DISEASES.

BY S. G. WEBBER, M. D.

TREATMENT OF PARALYSIS AGITANS.

Albrecht Erlenmeyer[1] reports his experience in regard to the action of drugs in a severe case of paralysis agitans. The tremor was so severe as to interfere with sleep. One or two tablespoonfuls of the following procured sleep, but had no influence upon the tremor: —

R	Chloral hydrat.	7.5
	Morph. muriat.	0.05
	Aq. dist.	150.
	Arrac	50.
M.		

This amount lasted the patient about fourteen days. She took it one and a half years.

An infusion of *valerian*, 20 : 200, to which was added 25.0 *bromide potassium*, in doses of four tablespoonfuls daily, had a marked effect upon the tremor, which was diminished while this was used, but returned when it was omitted.

Curare 0.5, aq. dist. 15.0, acid muriat. gtt. 2, was given subcutaneously, one, two thirds, and finally an entire syringeful being used; 0.011, 0.022, 0.033 of curare respectively. The larger dose caused the tremor to diminish. The improvement continued about three days. The curare was repeated every five days.

The *galvanic current* from eight cells, used for ten minutes, and later fifteen minutes, the anode on forehead, the cathode on the neck, gave very favorable results, but when the treatment was discontinued the tremor returned.

R	Atropia sulph.	0.03
	Ext. secal. cornut.	1.00
	Exts. liquir.	q. s.
M. F. pil. 30.		

One of these taken daily controlled a troublesome sweat, and also diminished the tremor. After nine days this had to be omitted, on account of a slight toxic effect from the atropia. Later, it was taken again with the same result.

Crystallized hyoscyamin had no effect upon the tremor unless taken in such doses as to show the beginning of toxic effects.

Nitrate of silver had no effect.

OSMIC ACID IN NEURALGIA.

A. Eulenburg[2] was led by Neuber's experience in neuralgia with osmic acid, injecting one per cent. aqueous solution, to try the same remedy. He found that the injection of the above strength caused no unpleasant symptoms. He selected twelve cases of neuralgia in different cutaneous nerve districts of the upper and lower extremities, of the head, and body; most of these were fresh and not unusually severe cases. The treatment extended over one to six weeks; the number of injections in individual cases was three to fourteen. The solution used, one per cent., gradually became dark colored; even that could be used without injury. The amount injected was 0.5 of the solution, exceptionally 1.0. After the injection there is a slight temporary reddening or swelling in the immediate neighborhood of the injection. The injection was made *in loco morbi*.

Of twelve cases three were cured (no relapse within two to fourteen weeks); four more or less relieved; five were not benefited. The three cases cured were probably cases of neuritis or perineuritis.

Subsequently he used the drug in seventeen other cases; four cured (two sciatic, one lumbar, one intercostal).

OSMIC ACID IN EPILEPSY.

Wildermuth[3] has used osmic acid, or the potassic osmite, in cases of epilepsy with only slight success. In seven cases he found no benefit. In two cases improvement followed; in one of these the benefit was about the same as that obtained by the use of bromide of potassium. In the other case the gain was much greater; the patient, a woman, seemed to be idiotic, indifferent to her surroundings. The attacks were very severe. In 1876 she had 321, in 1881, 980; bromide of potassium had no effect upon the attacks. 7th January, 1882, she began to take 0.002 osmic acid in watery solution; later took three to five mgr. in pill. The bromide of potassium was reduced to 2.00. The attacks diminished in frequency.

	1881.	1882.
January	131	48
February	121	6
March	125	0
April	121	10
May	11	2
June	9	4
July to December	401	0

The mental condition improved greatly. In 1883 several slight attacks caused the bromide to be increased to 4. and 7. for a short time. Since then the daily dose has been bromide 2.00 and 0.004 of potassic osmite. No further attacks. The above cases were all chronic, intractable cases.

The dose was from two to fifteen mgr. a day in pill, each containing 0.001 of the acid or the potassic salt; he prefers the latter.

PARALDEHYDE.

Carl von Noorden[4] gave between 3.0 and 6.0 grammes, with equal parts of inf. cort. aur., in a half wineglass sugar and water. He saw no evil effects, even from larger doses. Sleep followed in fifteen to forty-five minutes, and in favorable cases continued five to six hours; if accidentally awaked the patients went to sleep again.

Occasionally the taste and smell of the drug remained unpleasantly after waking, but generally no bad effects followed. As contraindication he mentions severe gastric disease and advanced phthisis, with affec-

[4] Paraldehyd als Schlafmittel. Cbl. f. kl. Med., 22 March, 1884, p. 185.

tion of throat. Among thirty patients he found only two who were nauseated or had headache from the use of the medicine. Patients with weakened heart bore the drug well, and obtained rest; the arterial tension was not diminished.

E. Kurz [1] reports his experience with paraldehyde in twenty-four cases. The dose was three grammes, sometimes four. The sleeplessness was due to different causes. It failed only in four cases. In no case did it have an exciting effect. The sleep began within half an hour after taking the dose, and lasted five to seven hours, sometimes interrupted. Headache did not follow its use; it was not necessary to increase the dose. It causes a very natural sleep, and is of most value when the sleeplessness is not caused by pain or mechanical disturbances, as coughing, dyspnœa, etc. The chief indication is the same as for chloral.

Langreuter [2] has used paraldehyde and acetal to produce sleep, the former in doses of six grm., the acetal in doses of ten grm. Acetal is less pleasant in its action, and is weaker than paraldehyde. As vehicle he used olive oil with oil of peppermint. Both drugs were used for months without unfavorable effect. The taste and odor are unpleasant. When given at bed-time paraldehyde was successful in causing sleep in ninety per cent.; when given during the day in sixty-one per cent. Sleep occurred in five to thirty minutes after taking the dose.

CEREBRAL CHANGES IN DELIRIUM.

Mr. Handfield Jones [3] gives three cases attended with delirium, one of phthisis, one of typhoid fever, and one choreic, in which the microscope showed the presence of active interstitial inflammation of the cerebral cortical gray substance.

CEREBRAL TUMOR.

C. Wernicke [4] reports the case of a patient who had the general symptoms of cerebral tumor, — extreme headache, choked disk, fainting fits, vomiting, and, later, overpowering sleepiness. The focal symptoms were a slight left hemiparesis, which might, however, have been indirect, bilateral anosmia, and total blindness. From the total blindness, which he considered the most important symptom, Wernicke reasoned that, with retention of the pupillary reaction, there was probably destruction of the fibres of the corona radiata, which run backward from the posterior part of the internal capsule to the occipital lobe, that the conducting power of these fibres was lost on both sides, either by two tumors, one in each occipital lobe, or by one tumor which extended into both lobes, or by pressure caused the interruption of conduction on both sides. At the autopsy a tumor was found in the right temporal lobe; the softening of the cerebral tissue extended so as to destroy the fibres of the corona radiata running to the occipital lobe on the right, but the occipital lobe and those fibres were intact on the left. The left optic tract, however, was compressed or strangulated by the posterior communicating artery, which was tightly stretched across the tract in consequence of the amount of fluid which was in the ventricle. Wernicke explains the reaction of both pupils by the fact that the fibres from the right optic tract, which was healthy, pass to both eyes.

THOMSEN'S DISEASE.

Schönfeld [5] reports a case of this peculiar affection; the patient was a soldier. Schönfeld thought at first that the patient was simulating, but soon found that that was impossible. The soldier was twenty years old; he had never been ill until his fourteenth year, when he was bitten by a dog. He referred his affection to the shock from fright received at that time. Soon after recovery from the injury he began to complain of weakness in his legs, so that after standing long, or after much labor, he fell, but did not lose consciousness. Sometimes when he stepped on solid substances his legs suddenly became stiff, and he was obliged to stand still to avoid falling. The arms had never become stiff. When the patient was caused to stand still in one spot for ten minutes and then told to walk quickly, he could not do so, but slowly and with evident exertion raised one leg, which bent to an angle of about 120° at the knee and hip, and, standing very unsteadily on the other, he set it down again in nearly the same angle. If he then raised the other leg he often fell, generally on the knee, with his arms outstretched, rarely backwards. Consciousness was not disturbed. He lay about five minutes, and then with great difficulty rose. If he did not fall he walked very unsteadily; the hip and knee were bent at an angle of 120°, and remained thus flexed during walking, the limb not being extended. The point of the foot was drawn strongly downwards, so that the great toe almost touched the ground, as in spastic spinal paralysis. The impression was given that all the muscles of the lower extremities were in a state of moderate contraction, and the predominating power of the flexors caused the limb to assume the above position. After ten or twelve steps the gait improved, and soon became natural.

When the patient had been sitting quietly a while there was the same difficulty in walking, and passive motion met with resistance, which was the more marked the more rapid the motion.

When the arms remained some minutes hanging passive by the side there was a difficulty in moving them similar to that found in the legs. The same peculiarity was noticed in the fingers and the eyes; speech was slow and drawling.

ATAXIA OF PERIPHERAL ORIGIN.

J. Dejerine [6] reports two cases which very closely resembled locomotor ataxia, in which he found no change in the spinal cord nor in the nerve roots, but extensive changes in the cutaneous nerves.

The clinical characters in his cases were, as to sensation, rather severe pains, some fugitive, some permanent, the first resembling in their spontaneity and quick subsidence the fulgurant pains of ataxia; the others were more durable, and were seen as lively suffering in the limbs, analogous to sciatica, but they did not follow any determinate tract, appeared also in the trunk, and the whole body except the face.

The objective change of sensibility was pronounced,

[6] Étude sur le nervo-tabes périphérique (Ataxie locomotrice par névrites périphériques, avec intégrité absolue des racines postérieures, des ganglions spinaux et de la moelle épinière.) Arch. de Physiol., 1884, p. 231.

there was anæsthesia, analgesia, and retardation of sensation. In his second case the anæsthesia and analgesia were very marked over the whole surface of the body except the face; also the sense of temperature was affected much earlier than is usual in ataxia.

The loss of motor power was real, and greater than is seen in ataxia, though not very marked. The incoordination was extreme, and in his second case was noticed in the upper as well as the lower limbs.

The patients could not with their eyes shut recognize the position of their limbs. The tendon reflexes were absent; there was no paralysis of the sphincters of the iris, and no myosis; in one case muscular atrophy and diminished faradic reaction.

The rapid progress of the disease is of great diagnostic value. In a few months the symptoms resembled those found in a case of confirmed ataxia.

The author considers that the loss of motor power and slight muscular atrophy, with diminution of faradic contractility, are most valuable for diagnosis; when these symptoms are met in ataxia it is only after the disease has continued a long time.

The only lesion found was a parenchymatous neuritis, the cutaneous nerves being most severely affected.

JUVENILE FORM OF MUSCULAR ATROPHY.

W. Erb[1] reports several cases of muscular atrophy commencing early in life, progressing slowly, which have certain peculiarities. His conclusions are: "There is a special form of muscular lesion, consisting in part of hypertrophy with subsequent atrophy (or the atrophy may be established in the first place), in part of hyperplasia of the interstitial connective tissue, and completed by a greater or less formation of fat tissue. It is uncertain whether the changes in the muscular fibres or the connective tissue is the primary. The peripheral nervous system, as well as the spinal cord, offers no recognizable change of structure. This is a very chronic, slowly progressive affection. As result every muscle attacked may appear now atrophied, again hypertrophied, or the subject of pseudo-hypertrophy.

Clinically the disease is characterized by a most marked and ever-recurring localization of the muscular lesion (in the upper part of the body, especially the pectorales, cucullares, latissimi, and other muscles of the scapula, the flexor group on the arm, including the supinator longus, triceps, etc., the fore-arm and hand are not affected; in the lower part of the body the lumbar extensors, a portion of the abdominal muscles, those of the thigh, then the peroneal region and calf in part). There is absence of the fibrillary tremor and of the degenerative reaction, and of all nervous or other disturbance. This disease begins most frequently in the upper part of the body, occasionally in the lower, according to the age of the patient. Most of the cases of this affection have heretofore been considered progressive muscular atrophy, a part pseudo-hypertrophy.

"The disease appears in the form of a progressive muscular atrophy in childhood, or youth (some time before or after puberty), and then forms what I first described as 'juvenile form of progressive muscular atrophy.' Not rarely it occurs in 'family' groups through many generations.

"When it begins in earliest childhood, and without marked lipomatosis, it is the 'hereditary muscular atrophy;' but if it is in this case combined with early and marked lipomatosis (especially of lower limbs) it is the 'pseudo-hypertrophy.'

"But all these forms are identical, and are the same disease, only with different modes of commencing, or course, or degrees of intensity.

"This affection is to be sharply differentiated, clinically as well as anatomically, from the spinal form of progressive muscular atrophy."

VISCERAL NEUROSES.

Dr. T. C. Allbutt[2] commented first upon the large number of cases of dyspepsia not due to organic gastric disease which are of nervous origin. It is quite common to overlook the neurotic character of these symptoms, yet the same is true in regard to other viscera. Many uterine disturbances are due to the general condition of the system rather than any local disease.

Dr. Allbutt mentioned several illustrative cases, and condemned hasty diagnoses, leading to error in treatment.

Gastralgia is not only found in women, but is common also in men, but only in one half the number. It is found at all ages from fourteen to sixty, but is most common between twenty and forty-five. Like migraine it tends to die out in middle life, and, like migraine again, it is attended less and less with vomiting as age increases. Gastralgia comes on earlier in woman than in man. In man it is rare before the twenties; girls often have it in their teens. Migraine is by far the most common associated affection. Eighty per cent. of the author's cases had both. The two affections usually alternate one with the other. Asthma is often associated with gastralgia. Like asthma gastralgia is often nocturnal, and is aroused by improper food or by any food. Hence the persistent confusion of gastralgia with dyspepsia. The cardiac neuroses are found associated with both these vagus neuroses, including true angina. Pseudo-angina is quite frequent with gastralgia; of this several examples are given.

Cervico-brachial and intercostal neuralgias are also found associated with gastralgia. Yawning is another curious symptom which occasionally occurs with gastralgia. There may or may not be vomiting. The vomiting allied to migraine is more common in the morning, is more periodic, and recurs at longer intervals; that allied to gastralgia is more dependent upon ingestion of food, irregular in recurrence, may be daily or almost incessant. The former is encephalic, the latter is reflex.

Several cases of gastralgia with pyrosis, flatulence, and vomiting are given. The author thinks that these cases of vomiting with gastralgia have often been called hysteria.

Gastric neuroses are not specially frequent at the catamenial period. Vomiting blood complicates the case and renders diagnosis less easy.

Anorexia may become so great as to amount to a disgust for food, and the patient may eat so little that emaciation becomes extreme.

In *enteralgia* the pain is in the umbilical region, about two inches to one side, usually the right, or in

[1] Ueber die "juvenile Form" der progressiven Muskelatrophie und ihre Beziehungen zur sogenannten Pseudohypertrophie der Muskeln. Deut. Arch. f. kl. Med., xxxiv., 1884, p. 467.

[2] The Gulstonian Lectures on Neuroses of the Viscera. British Medical Journal, March 15, etc., 1884.

the right flank a little higher than the iliac fossa. He thinks it is not rarely of gouty nature, is aroused rather by the strife of public life than by the teasing of homely worries.

The pain is severe, the bowels are seldom disturbed. He hesitates to place the seat of the pain in the bowels. Sometimes a rough periodicity marks the recurrence of the attacks.

The pain of lead colic is diagnosticated by its being more diffused than the pain of enteralgia, and not limited to *lieux d'élection;* it is not often an excruciating, nor a slashing pain; it is rather of a grinding or fretful character. The parallel constipation and other circumstances serve also to distinguish lead colic.

Hepatalgia is referred to the presence of gall-stones at rest in the gall-bladder in an impressionable or neurotic patient. But the diagnosis of this and the remaining visceral neuralgias he considers to be very difficult.

Allbutt briefly notices the frequent association of neuroses of the vagus with certain kinds of eczema, lichen, and psoriasis, with eczema and lichen chiefly, and the question as to gout being the cause of both the skin eruption and the vagus neurosis. He also refers to a rheumatic taint as a pos-ible cause.

In speaking of treatment, Allbutt mentions that the neurotic has no reserve. When once the natural reserve has been dissipated it is never reaccumulated. This reserve may have been spent in beneficent activities, or it may have been dissipated in fidgets, fretfulness, or shrewishness; in sleeplessness, in anxiousness, or in pain, according to the quality of the person. To trade daily only upon the supplies of the day is to court collapse; we must have more brain, more spinal marrow, more liver, more kidney than we want for the day. We must have stored up force, partly for greater occasions, partly to secure the equable running of our machinery. In the early life of neurotic subjects we must favor the accumulation of nerve force by controlling expenditure and cherishing nutrition.

In an exhausted neurotic the secret of treatment is — by food, fresh air, exercise, and happiness — to lift up the patient from the invalid couch, to teach him so to manage expenditure, and so to promote nutrition as to replace his capital.

The necessity of feeding well, even at the expense of some pain, is dwelt upon at length. Release from toils or worries, change of air and scene are advised. Inland resorts are better than the sea-side for gastralgics. High mountains are not favorable.

The only things to be forbidden are tea, coffee, tobacco, and the stronger meats, such as beef; alcohol is not to be encouraged; so of morphia, though severe cases cannot be treated without the latter.

Arsenic takes the chief place among drugs.

Small blisters to the epigastrium, often repeated, are of service. Quinine, boldly pushed, with belladonna form a valuable combination. So do quinine and bromide of ammonia dissolved in hydrobromic acid. The infusion of *prunus Virginiana* makes an excellent vehicle.

The silver salts are of undoubted use.

Allbutt has found iron of comparatively slight value.

Phosphorus is not of value, but the compounds of hypophosphites often are.

Cod-liver oil should be added as soon as it can be borne.

In enteralgia arsenic is of less value than in gastralgia; quinine and belladonna seem best.

Reports of Societies.

PROCEEDINGS OF THE OBSTETRICAL SOCIETY OF BOSTON.

C. M. GREEN, M. D., SECRETARY.

MAY 10, 1884. The President, DR. C. ELLERY STEDMAN, in the chair.

GASTRO-NEPHRIC FISTULA.

Brief notes of a case of this extremely rare lesion were read by DR. J. R. CHADWICK, who reserved a full report until the case should be made complete by an autopsy.

A married lady, sixty-two years of age, had had attacks of gastric colic, with vomiting, at intervals of one to six weeks for seven years. She had had frequent micturition for a year and a half, and had seen particles of food in her urine. She entered his private hospital on November 12, 1883, when the abdomen was found to be generally tympanitic, except in the upper part of the right lumbar region, where a resisting, tender body was felt protruding from beneath the ribs like an enlarged kidney. Turbid urine was drawn from the bladder, the flow being occasionally interrupted by solid particles and by bubbles of gas. This urine was found by Prof. E. S. Wood to contain a "trace of albumen, much pus, a little blood, muscular fibre, boiled potato, vegetable fibre." The examinations of the urine were made for many consecutive days by Professor Wood with essentially the same results. As the attacks of colic were apparently confined to the stomach, as the tumor was in the region of the right kidney, as the particles of food found in the urine were invariably undigested, and above all as no trace of bile was found in the urine, except for three days following an attack of vomiting, the diagnosis of gastro-nephric fistula was thought warrantable. This was accepted by Drs. G. H. Lyman and C. E. Stedman, who saw the patient in consultation. Various diets were tried without effect, so that after a month the patient was sent home to Rhode Island unrelieved, as her condition did not warrant a resort to the very hazardous chances of an operation. Dr. Chadwick had found in medical literature the reports of but two authentic cases of this lesion; one in a French thesis of 1856, where a gastro-nephric fistula had been discovered post mortem, but no history of its course recorded; the other in an Italian journal published in 1866, where no confirmation of the diagnosis by autopsy had been reached at the time of publication. The probable origin of these lesions is in purulent nephritis.

DR. LYMAN said the case was one of the most interesting that he had ever seen: it was wonderful that the woman had maintained her nutrition so well. He inquired if the woman had been fed by rectum.

DR. CHADWICK replied that she had not. It was found that liquid food given by stomach escaped without much change through the bladder: hence it was thought best to give solid food which remained longer in the stomach. At one time there was much gas discharged by the bladder.

DR. ABBOT asked if the urine had been examined at times of long abstinence from food, and compared with the urine passed soon after taking food, with a

view to determining whether the fistula was gastro- or intestino-nephric. The reply was that no such experiment had been tried.

CRANIAL BONES OF A FŒTUS REMOVED FROM THE RECTUM.

DR. DOE reported the case[1] and showed the specimen.

DR. LYMAN asked what amount of inflammatory action was going on. The reply was that there was no febrile movement at the time.

DR. J. W. ELLIOT reported

A CASE OF DOUBLE UTERUS AND VAGINA.

The patient was thirty-four years of age, had been married sixteen years, and complained of sterility, constant pain in the lower part of the abdomen, dysmenorrhœa, mental depression, and nervous spasms. On April second she entered Dr. Elliot's private hospital and was examined under ether. There were two separate vaginæ, both slightly smaller than usual: the septum, about one eighth of an inch thick, began just behind the hymen. At the end of each vagina was a cervix slightly smaller than normal. A probe could be passed into each cervix. The bimanual examination showed distinctly that there were two independent uteri: both were enlarged; one anteflexed, the other in about the normal position. The patient was afterwards seen during menstruation, and the menstrual flow came from both uteri.

DR. DAVENPORT asked if examination had been made by rectum.

DR. ELLIOT replied that rectal examination gave the same result as by vagina: the finger passed behind both cervices and felt the double fundus above; without ether, however, nothing could be felt but the double cervix.

DR. CHADWICK expressed skepticism as to whether a double uterus could attain such a size as the reader had stated, since the double uterus was usually an arrested development and therefore smaller than the normally developed uterus.

DR. ELLIOT said that the size of the double uterus was large in this case: he thought the bodies were dilated by fluid, there being stenosis at the ora interna. The menstrual flow is profuse.

Dr. Elliot also reported

A CASE OF RETROVERSION OF THE GRAVID UTERUS.

He was called to Mrs. E. in Brookline on March 9: he found the family much alarmed, and the patient in a critical condition. She said that she was twenty-three years old, that she had been married three months, that the catamenia had not appeared for the last two months. Three weeks before he was called, the patient began to vomit: for the first week she could retain a very little simple food; for the last ten days she had retained almost absolutely nothing. She had been under the care of a homœopathic physician who had not succeeded in relieving her. A female homœopathic gynæcologist had relieved her for one day by the use of a soft rubber ball pessary which had soon caused flowing and was therefore removed.

When Dr. Elliot saw her she was very thin and worn, and was tossing about the bed in a state of extreme nervous and physical exhaustion. She was retching and spitting incessantly, even when not attempting to take food. On examination he found the uterus somewhat enlarged, very low in the pelvis, and retroverted. She was flowing. There was evidently retroversion of a pregnant uterus, and a beginning miscarriage caused by the pressure of the soft rubber ball pessary. He pushed the uterus up out of the pelvis and directed her to lie in the semi-prone position: this relieved her for a time; but in the afternoon of the same day she sent for him again, and he found her vomiting as badly as before. He found that the uterus had partially retroverted again but the flowing had stopped. He put the patient in the knee-chest position and replaced the uterus without difficulty. He then placed a pessary which held it in position: the vomiting ceased entirely almost immediately and has never returned. The patient was able to take food every hour, and on the second day took two quarts of milk. She regained her strength very rapidly and is now in prime condition. He removed the pessary in about two months, when the uterus had grown so large that it could not retrovert. Although the vomiting was entirely relieved by the replacing the uterus, the spitting continued to trouble her more or less for several months.

DR. FIFIELD asked whether, when the patient was placed in the genu-pectoral position and the perinæum was retracted with a Sims' speculum, the uterus replaced itself.

DR. ELLIOT said that it was necessary to draw down the cervix with a tenaculum and then push the fundus into place.

DR. CHADWICK asked the reporter if he ever saw the uterus replace itself with the patient in the genu-pectoral position.

DR. ELLIOT said no, unless the blade of the speculum is long enough to push the fundus forward.

DR. CHADWICK thought the knee-chest position a poor one for replacing a uterus. If the cervix is hooked down, the uterus can be replaced; but he disbelieved in hooking down the cervix. He had raised the fundus by inflating the rectum; but he now places the patient in an erect posture, when the uterus sinks, and, when the vagina is lax, can be easily replaced. He thought the erect position far better than the genu-pectoral.

DR. ELLIOT saw no objection to the use of the tenaculum and believed the knee-chest position a good one, when it was desirable to use as little manipulation as possible.

CONCERNING THE ÆTIOLOGY AND PATHOLOGY OF HYDRAMNIOS.

DR. C. M. GREEN read a short paper[2] on this subject.

DR. BENJ. CUSHING, present by invitation, alluded to the methods now advocated for removing the placenta after abortion. He had formerly given ether and introduced his hand or had employed placental forceps; but for the past twenty years he had employed with good results an instrument of his own device which was essentially a small scoop or spoon with a long handle. He could use this scoop whenever the os was sufficiently dilated to allow the intro-

[1] See page 268 of this number of the JOURNAL.

[2] See page 267 of this number of the JOURNAL.

duction of his finger, and he believed the instrument was far better than placental forceps.

DR. CHADWICK had used the scoop for the last four or five years with great satisfaction: he thought it contained all the value of Thomas's serrated scoop.

DR. FIFIELD also testified to the value of the instrument. He seldom gave ether. He disbelieved in too early and too persistent search for the placenta and thought a little waiting and a little ergot would often bring away the placenta without trouble. It was his practice, in abortions from the second to the third month, to tampon the vagina and wait for twelve hours; then to place the patient on a bed-pan and give a vaginal douche: he usually found the placenta in the bed-pan. In abortions later on it was his custom to wait until the os was sufficiently dilated to admit the scoop or the finger.

CHICAGO MEDICAL SOCIETY.

LISTON H. MONTGOMERY, M. D., SECRETARY.

STATED meeting, September 1, 1884. DR. A. K. STEELE in the chair.

DR. J. A. ROBISON read some

REMARKS ON ANEURISMS,

of which a few of the principal points are herewith appended, omitting reference to the ætiology, pathology, or diagnosis: —

The general principles governing the treatment have been to prohibit the patient from taking much exercise, to secure as nearly as possible absolute rest, and to restrict the diet. When the heart was tumultuous cardiac sedatives were exhibited and such symptoms as dyspnœa, pain, etc., have been met with appropriate palliatives. The first attempt at specific treatment for internal aneurisms was employed many years since by Albertini and Valsalva, and has been known as Valsalva's method. It consisted in weakening the patient by repeated blood lettings, and by gradually diminishing his meat and drink till only half a pound of pudding was taken morning and evening, with only a measured quantity of water, so that at last the patient was so exhausted he could not lift his hand from the bed in which he was ordered to lie from the commencement of the treatment. When this stage was reached the amount of nutriment was increased until the patient's strength was restored, but this plan of treatment did not yield the beneficial results which were anticipated. In our day it would be regarded as barbarous were we to try and enforce this treatment to the extreme which Valsalva reached. A modification of this method, consisting of enforcing absolute rest, and diminishing the food and drink, so as to diminish the quantity but not the physiological quality of the blood, has benefited a number of cases, if not entirely cured them. While some physicians have refused to employ the depleting treatment, they have resorted to measures fully as severe. Dr. Murchison and Mr. Moore, of England, have recommended, and in one case tried, the introduction of fine wire into the aneurismal sac, on the theory that the large amount of surface exposed to the circulating fluid would produce coagulation of the fibrine. In the case referred to they introduced twenty-six yards of fine iron wire into the aneurismal sac, and it is needless to say that the treatment was unsuccessful, although they contend that the result obtained demonstrated the principle was sound, and that further experiments were justifiable. A much less dangerous and probably more efficient mode of treatment is by electrolysis. Pravaz was the first to use electrolysis for reducing external aneurisms, and Cinicelli and others have applied it to internal aneurisms, but with very indifferent results; in eight cases of thoracic aneurisms only one was benefited, only one case of abdominal aneurism was cured, and this patient died from rupture of the sac on account of premature exertion. The results obtained from the use of the galvano-puncture have not justified us in hoping for much from that method. Professor Langenbeck has published accounts of two cases which he claimed to cure by hypodermic injections of one half to three grains of Bonjean's watery extract of ergot every three days; Balfour says he has tried this method frequently, but without any success, although he was positive that his ergot was active. Pressure as a mode of treatment is wholly inapplicable to thoracic aneurisms, and rarely to abdominal. Dr. Murray records a case of the latter, in which pressure on the aorta for five hours, the patient being under chloroform, was successful.

Treatment of internal aneurisms by the administration of the iodide of potassium is conceded by Flint and Bramwell, and Balfour insists that the iodide of potassium is the only drug which offers any hope of cure, and in every case it will relieve the distressing symptoms. This author says: "Of all the various modes of treating internal aneurism, there is not one hitherto mentioned which is not attended with considerable risk or danger except Mr. Tufnell's plan of perfect rest, while the advantages to be derived from some of them are, to say the least, very problematical."

The reader claimed that the treatment by the iodide of potassium is perfectly safe and free from all risk, and it is equally certain to afford relief, although relief is not always to be gained instantaneously. It relieves the pain and other symptoms of aneurisms more rapidly and more effectually than any other treatment, apart even from the powerful agency of the recumbent posture. The relief to the pain and other symptoms is so great and so speedily obtained, usually from the action of the drug alone, that it is often difficult to get the patient to submit to any restrictions. The author has employed this method of treatment during the last eight years in a very considerable number of cases with unvarying success so far as the relief to symptoms is concerned, and with such favorable results as to retarding the further progress of the case, and even in some cases promoting an apparent cure, as certainly to stamp this treatment as one of the most efficient hitherto propounded for the relief of this intractable complaint. Balfour relates the history of twelve cases treated by this method with the following results. The symptoms, such as pain, dyspnœa, etc., were relieved in every case: The physical signs of aneurism were diminished in seven cases, pulsation of the tumor ceased in two cases, diminished in four, and was not apparent from the commencement in six. The aneurismal tumor disappeared in three cases and diminished in five. The bruit disappeared in two cases, and diminished in two cases, but never existed in two cases. Five of the patients were so relieved that they could work, four were discharged at their request, feeling well; one patient absconded, and the result of treatment is not known.

Five cases were termed cured, and seven were relieved; one of the twelve cases referred to was an aneurism of the innominate artery, which was cured, and Balfour claims to have cured several cases of aneurism of this artery. One of the four cases discharged at their own request was under treatment three different times, being discharged twice at his own request, but died suddenly while under the third course of treatment, the autopsy revealing an aneurism of the aorta which had ruptured into the lower lobe of the right lung. One of the twelve cases was diagnosticated as a weeping aneurism, implicating the origin of the left carotid, and communicating by a small opening with the left bronchus, the patient on admission expectorating arterial blood, but this soon ceased and the patient was discharged cured.

While the writer did not believe he was justified in being as enthusiastic in the praise of the iodide of potassium treatment as Balfour, he believed he was justified in relating the following case, and giving the iodide of potassium the credit of prolonging the patient's life and making his days comparatively comfortable: —

John H. C., aged forty, a blacksmith, was first seen March, 1883. Had had attacks of inflammatory rheumatism several years previously. In February, 1883, he was attacked with severe pains in the chest in the præcordial region, and was treated by his physician for rheumatism for some weeks, when Dr. J. P. Ross saw him, and diagnosticated aneurism of the aorta. At this time the patient had a good deal of dyspnœa, some hoarseness of the voice, and quite a little difficulty in swallowing solid food. When fatigued the pains in his chest were excruciating. No tumor was perceptible, although there was pulsation in the upper sternal region, and dullness upon percussion over the area of pulsation. Two months afterward there was a swelling in the upper sternal region at the junction of the left first and second ribs, about the size of a silver dollar. A very slight bruit was heard. The voice was very husky, and the difficulty of deglutition had increased until now the patient could take no solid food whatever. He was emaciated and was losing strength very rapidly. He was ordered to lie in bed continuously, and was given fifteen grains of the iodide of potassium three times daily, gradually increasing the dose until signs of iodism appeared. It was truly remarkable how soon after this plan of treatment was inaugurated the patient expressed himself as free from pain, and the distressing symptoms from which he had suffered. He persevered until May, when he said he was so well and weary of the bed he would like to sit up. Leave was granted, and a few weeks after the writer was surprised to see him walk into his office. He complained of nothing, but he was cautioned against such rash experiments, and was told to return home and take better care of himself. His condition at this date was as follows: The continued pulsation of the tumor against the chest wall had produced absorption of a large portion of the manubrium, and an inch of the inner portion of the left first and second ribs. Consequently we could feel the pulsations of the tumor through the chest wall at a point where only soft tissues intervened. No bruit was discernible. On laryngoscopic examination there was found complete paralysis of the left vocal chord. His voice was anserinous. During all these months he had been taking the iodide of potassium without any disturbing effects, until now, when he complained of symptoms of iodism. He was permitted to discontinue its use. From the date of this office visit the patient grew rapidly worse. Dyspnœa and dysphagia increased, and finally he died of asthenia July 19, 1884.

Autopsy. On opening the thorax a large aneurismal tumor was seen behind the sternum, about five inches in diameter. Friable adhesions of the sac to the sternum were broken up when the sternum was removed. Absorption of a large portion of the sternum and the left first and second ribs had taken place. Heart and pericardium were normal; adhesions between the aneurismal sac and the left lung; the left lung was pressed upward and backward into the left pleural cavity, and collapsed. On opening the heart the aortic valves were roughened; the arch of the aorta was dilated, and at the front of the arch, between the origin of the innominate and the left carotid arteries, was an opening, oval in form, one inch by one and a half, into the sac of the aneurism. Through this opening the wall of the aorta was continuous with the wall of the aneurism.

DR. E. T. INGALS was much interested in the case just reported, for he had also seen the patient. Last April he had been consulted and found all the symptoms present that have been described. The speaker cited briefly a case of aneurism of the abdominal aorta which he treated five or six years ago by iodide of potassium two thirds of the time for two years, and as a result there was obtained loss of the bruit, cessation of pain, and the size of the tumor was reduced one half. He saw the case recently, and there has been no return of the difficulty. Another case quite similar, he treated three or four years ago in the same manner and the pain was relieved. A case of thoracic aneurism treated three years, by giving twenty grains of the iodide three times daily, did not result so favorably, for the patient died suddenly. He was at present treating a case of abdominal aneurism in which all the symptoms have improved, and the enlargement is reduced one half. He desired to ask of any of the members their views as to how long the remedy can be taken continuously, before it has an injurious effect on the mucous membrane of the stomach or kidneys? About a year ago he began treating a case of stricture of the trachea, by giving four hundred and eighty grains of iodide of potassium, freely diluted, for some time daily until symptoms of iodism appeared, and he found the stricture was being absorbed, when sixty grains of the remedy was ordered to be taken three times a day. This was continued for six months; then five grains, three times daily. This amount the patient has been taking almost continuously during the past few months.

DR. JOHN BARTLETT cited a case of general chronic bronchitis and asthma in a man seventy years of age. Eight years ago he began treating him by the administration of iodide of potassium in eight-grain doses, three times daily, and not a single day has he omitted to take the medicine down to this time; as a result the patient has steadily gained in flesh, grown fatter and stronger, his appetite is not impaired, and his kidneys perform their normal function.

DR. ROBISON concluded by stating that Balfour does not administer as large doses now, at the beginning of the treatment of a case of any form of aneurism, as he used to. That fifteen or twenty grains three or four times a day is about the quantity he gives, then

when the pulse is quickened or the heart becomes irritable the remedy is stopped temporarily.

DR. H. M. SCUDDER read a paper on

THE TREATMENT OF ASIATIC CHOLERA IN SOUTHERN INDIA,

whose contents possess the more interest from the fact that the writer was for nine years a resident in India and passed through four epidemics of cholera there, and himself had the disease. Dr. Scudder was the only European physician in a town of nearly 50,000 inhabitants, and was at the head of a district hospital supported by the English government, and treated a large number of cases. One of the severest of these epidemics occurred during the famine of 1877 and 1878. He was assigned to take the medical charge of a large inclosed famine relief camp containing over five thousand persons, where there were often as many as three hundred at a time in the hospital sheds with a death roll during the height of the epidemic of over fifty per diem. In this camp the writer had the opportunity of trying on an extensive scale different remedies and the various modes of treatment, and comparing the results. The description of the treatment is therefore confined to the methods employed of late years in Southern India. Before proceeding to this, the writer stated his views in regard to the contagiousness of the disease. In India, he said, it is generally considered that cholera is an infectious disease and also somewhat contagious, though not highly contagious or readily communicable by personal association with the sick, as is the case with small-pox and measles. The noxious power of the cholera germ or virus (whether it is Dr. Koch's microbe or something else) seems to be more powerfully exerted some time after it has escaped from the body of the patient than when it is freshly passed. His own careful observation in the epidemics that he had passed through, and experience the world over, seems to establish this fact, yet the contagiousness of the disease still seems to be a vexed question, and remains yet to be decided. The writer further stated that from his experience and the careful study of the history of Indian epidemics he is led to believe that the attendants and those who come into frequent and close contact with cholera patients are somewhat more apt to contract the disease than those who do not.

For purposes of treatment, the writer divided the course of this disease into the following stages: (1) a period of prodromes or prodromic stage; (2) a first stage or stage of diarrhœa or cholerine; (3) a second stage or stage of invasion; (4) a third stage or stage of collapse (algid state); (5) a fourth stage or stage of reaction; this last stage may be succeeded by a typhoid condition, or cholera typhoid state, or the patient may pass directly into a state of convalescence.

In the prodromic stage, manifested by lassitude, mental depression, chilliness, nausea, and abdominal discomfort, give ten or fifteen drop doses of spirits of camphor in dessert spoonfuls of hot brandy every hour or two, but be careful not to allow any considerable quantity of stimulants to be taken When epidemic cholera is prevalent many are affected by the symptoms just described. If the remedies indicated were promptly taken the writer was confident that many attacks of cholera would be warded off. It is true that fear often produces these very symptoms, but the spirits of camphor in spoonfuls of warm brandy tends to soothe the fears and dissipate the symptoms, and yet it does not usually disorder the digestion.

As soon as diarrhœa supervenes begin the administration of some preparation of opium, together with aromatic camphor; a little chloroform is then urgently called for. Two parts of chlorodyne to one of spirits of camphor is a very good combination, thirty drops for a dose, to be repeated as required. Another very serviceable preparation consists of equal parts of spirits of chloroform, spirits of camphor, laudanum, aromatic tincture of rhubarb, and tincture of ginger. Teaspoonful doses every hour or two, according to the urgency of the case, or until four or five doses have been taken, alternated with either of these combinations: an aromatic sulphuric-acid mixture or the following popular formula: —

℞ Acid. sulphuric aromat. . . . . ʒi.
Tinct. opii deodorat. . . . . ʒvi. vel ʒi. M.
Sig. Twenty or thirty drops in water every hour or two.

The writer suggested the importance of administering these remedies hot unless they create nausea. The hot water (two or three tablespoonfuls) in which the doses are given may be sweetened if desired. The patient should be required to lie down, and kept perfectly quiet, covered with heated blankets, and dry heat applied to the surface of the body, especially to the extremities, by means of hot bottles, heated flatirons, etc.

In India the administration of calomel to any extent has been lately discouraged. One or two doses may be given if thought best, but not more. As soon as frequent vomiting commences, or the stage of invasion becomes established, the combinations containing opium which have been mentioned had better be discontinued, and either of the following mixtures given instead, in teaspoonful doses to check vomiting, while at the same time some morphine, or morphine combined with chloral, should be administered by hypodermic injection, as the severity of the case may demand: —

℞ Chloroform,
Tinct. capsici,
Tinct. cannab. ind., ... āā ♏xxx.
Acid hydrocyanic (dil.) . . . . . ♏xx.
Ether . . . . . ♏viii.
Spts. menthæ pip. . . . . ♏ xv.
Syrup sassafras. comp. . . . . ad ʒii. M.
Sig. A small teaspoonful every half hour or hour.

or

℞ Spts. ammoniæ aromatici,
Spts. chloroformi,
Tinct. capsicum,
Comp. tinct. cardamon, ... āā ʒi.
Tinct. ginger,
Sig. Give in the small doses as above.

A mixture of aromatic powder, gum arabic, and acetate of lead, may also be given alternately with either of these, if desired. In any case mustard plasters should be applied over the stomach and abdomen, but not left on too long; and, if required, enemas of eight or ten grains of acetate of lead may be given after each evacuation. The writer further stated that it was important to bear in mind that some preparation of opium or morphine, combined with chloral, is the chief remedy for cholera, and the surest agent we can use to arrest the progress of the disease. When called, therefore, to a case already in the stage of invasion, morphine, or morphine and chloral, should be administered hypodermatically, without delay, in order to get these sovereign remedies into the system as soon as possible; for if we can arrest the disease before the

patient become collapsed his chances of recovery will be greatly increased.

Caution must be exercised, however, when this form of treatment is pursued, for narcotism is easily induced by repeated hypodermic injections, whereas very large doses of opiates can be given in this disease by mouth and rectum with comparative impunity. The strength of the solution usually employed for injection is: morphine, gr. iiiss. vel gr. iv., with chloral hydrate, ʒiiss. vel ʒiii., to the ounce of water. Inject twenty or thirty minims. The hypodermic use of morphine and chloral is, of course, contra-indicated when the stage of collapse has become developed.

During this stage it is most essential that the patient should be kept perfectly quiet, and in the horizontal position. No violent rubbings should be allowed, but the writer had found it beneficial to gently rub the limbs and extremities with hot oil.

To allay thirst let the patient suck ice frequently. Carbonic-acid water or simple acidulated effervescing drinks may also be given by the tablespoonful. It is unsafe to allow the patient to drink any fluid whatsoever in large quantities. In this stage, especially when the acts of vomiting and purging have become less frequent, and the algid state well developed, very small quantities of stimulants are useful, but they should be given with great caution lest vomiting be provoked. Stimulant enemas may also be given, but where the stomach has an inverted action it is often better to inject small quantities hypodermatically. Experience teaches that anything like the free use of stimulants in cholera is uncalled for and exceedingly harmful. They may, however, be given in small quantities in the prodromic stage, and in the stage of collapse. The reader has sometimes used small doses both of atropine and strychnia, administered by hypodermic injection, apparently effectually, to bring about reaction. Amyl nitrite by inhalation may be given a trial, but it seems to exercise very little permanent or beneficial effect. Intra-venous administration of milk and salines may be resorted to, but the reaction they induce is not generally of a permanent character, so that many of those who have given this method a fair trial have abandoned it.

Of late years, in Southern India, careful experiments have been carried out in reference to the value of impregnating the atmosphere of the sick-room with sulphurous acid by the burning of sulphur. The result is that this procedure has been introduced as part of the treatment of cholera. The writer has on several occasions tried this plan by subjecting the inmates of two different cholera sheds to exactly the same conditions and treatment in every respect with the exception that in one the atmosphere of the shed was impregnated with sulphurous acid, and that in the other this precaution was omitted. He found that the proportion of recoveries was considerably greater in the shed where sulphur was used. He therefore considered this an important adjuvant as part of the treatment. The atmosphere should not be so highly impregnated as to cause the patient or attendants to cough violently. Sulphurous acid thus applied is not only a useful remedy, but it is also believed to decrease the possibility of the disease being propagated or contracted by the attendants.

During the stage of reaction great care should be exercised; vomiting often continues, and the normal absorbing power of the stomach and intestines is but slowly restored. Liquid nourishment by the spoonful should be most cautiously given, well salted broth and milk given hot as possible and not too frequently are the only forms of food admissible until the enfeebled stomach shows signs of recovering its tone. Peptonized beef tea and milk are frequently well borne, if carefully prepared so as not to nauseate the patient. If vomiting persists the following emulsion may be given if deemed best: —

℞ Acid. carbolic . . . . . gr. vii.
Bismuth sub nitrat. . . . . ʒii.
Mucilag. acaciæ, } . . . . . āā ʒi. M.
Aquæ menthæ viridis }
Sig. A teaspoonful every hour or two.

But in this stage it is good treatment to let nature do the work of restoration and give as little medicine as possible. We must bear in mind, however, that the kidneys must be assisted to resume their functions, and for this purpose mild diuretics should be carefully administered. If fever supervenes it is apt to be of a typhoid character; a combination of iodine and carbolic acid then exerts a beneficial effect.

(To be concluded.)

CHEESE POISONING.

The secretary of the Michigan State Board of Health, Dr. Henry B. Baker, reported at the last quarterly meeting of the Board, held at Lansing on the 8th of July, among other matters of interest, on the subject of cheese poisoning. The secretary presented a report on four outbreaks during the months of May and June at Middleville, Jerome, Jonesville, and Big Rapids. All of the persons who ate of the cheese in question, about 164 in all, were taken sick with the same symptoms, namely, pain and a burning sensation in the stomach, intense vomiting and purging, feebleness of the pulse, coldness of the extremities, and a tendency to collapse. All finally recovered. The cheeses were ordinarily good-looking specimens, but, when they were cut or broken, a liquid oozed into the pores. In each case the cheese was made at a factory in Fruitridge, Lenawee County.

Dr. V. C. Vaughan also read a report on the subject. At the request of the secretary he had visited the factory in Fruitridge, and had analyzed specimens of the cheese. Everything about the factory had appeared to be scrupulously clean, and nothing in the vats, the cans, or the surroundings offered an explanation of the cause of the poisoning. Analysis showed no arsenic, copper, lead, iron, or other mineral poison. When the cheese was cut or broken, a whitish liquid oozed into the pores, and in this liquid microscopic organisms were detected. The liquid was very strongly acid. For more than a hundred years, the report continued, the attention of the scientific world had been drawn to the subject of cheese poisoning by repeated outbreaks of this sort, both in this country and in Europe. Much had been written on the subject, and many investigations had been carried on, especially in Germany. By various observers the poisoning had been ascribed to diseased milk, decomposition, and the development of certain fatty acids, etc.; but we did not yet know what made the cheese poisonous. In regard to the cases under consideration the maker of the cheese had stated that the cheese which had produced the bad results had all been made between the 26th of April and the 26th of May, in the same manner and

with the same care as other lots which had given no cause for complaint. Good cheese was only very slightly acid, and was slow in reddening blue litmus paper, but the poisonous cheese was intensely acid, a freshly cut surface of it reddening litmus paper instantaneously. This test for poisonous cheese appeared to be practical, as the litmus paper could be applied by any grocer to a freshly cut surface of the cheese. If it was instantly turned red by the liquid which oozed into the pores the cheese was to be suspected of being poisonous.

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 18, 1884.

A Journal of Medicine, Surgery, and Allied Sciences, published weekly by HOUGHTON, MIFFLIN AND COMPANY, *Boston. Price, 15 cents a number; $5.00 a year, including postage.*

All communications for the Editors, and all books for review, should be addressed to the Editors of the Boston Medical and Surgical Journal.

COLLEGE ATHLETICS.

TWO papers were read at the meeting of the Social Science Association in Saratoga last week before the Section on Health, one by Professor Sargent, of Harvard, the other by Professor Hitchcock, of Amherst. The former gentleman alluded to the obvious and manifold advantages of properly directed physical culture to young men, particularly to students, but laid especial stress on the danger of the encroachments of professionalism with all its degrading influences on the field of natural healthful sports. The large amount of space devoted by the public press to "sporting intelligence" was strongly deprecated. In all sports the growth of the professional element marks the decline of the sport itself. When a man learns that his exceptional physical powers in any line have a money value, it is a temptation to use them in that line, and with him sport becomes a business. Then he loses his respect as a man very rapidly, and finds that he is like a horse or a dog, valuable only for the prizes he can win for his master, and he rapidly begins to look for success alone, no matter by what jockeying tricks or frauds it must be secured. The mercenary spirit is not confined to the athletes, but property owners, hotel proprietors, transportation companies, etc., all take an interest in athletics which is purely and wholly mercenary. Betting has always been and always will be the bane of competitive contests, not alone because it is wrong in itself, but also because of its demoralizing influence on all concerned. In order to controvert the law of chances and make betting a safe and paying business, "tips," "points," and "understandings" must be obtained, so that it becomes simply a disguised but sure robbery. Yet many of our young men are foolish enough to stake their week's earnings on a contest whose issue is known to the sharps that "bet" with them. Professor Sargent strongly favored athletic exercises in colleges, but wanted the evils eliminated. The first remedy suggested was that prominent educators and college officials should come to some agreement as to the part athletic sports are to play in a system of education. College faculties should announce their positions, and define them accurately, about the whole matter of athletic sports and training during the college course. Great good would come from the reform in the conduct of college sports recommended by the intercollegiate athletic conference which met last February. The question is no longer of simple physical significance, but has become of great moral and social importance, and the community at large must strengthen college faculties in devising common means for meeting a common danger.

Professor Hitchcock in his paper took even stronger ground than Dr. Sargent in his claim as to the obligation of the college to furnish physical training to its students. It is not enough, Professor Hitchcock says, for the Faculty of the college to enlarge upon the value of long walks, inspiring pure air, and an occasional bath, as the condition of the weather, the inducements of the natural surroundings, or the inclination or daily duties of the student may allow. In fine, then, the advanced idea of a college should recognize, as a part of its work, a supervisory care over the conditions of health in the student, and an education how to use the physical powers in harmony with the intellectual, by instruction and enforced attendance upon healthful, recreative duties, so far as to be able to maintain the highest power of the whole man, and keep them thoroughly active in the summer time of existence. In conclusion, he said the value of physical education is shown in the decrease of illness during college life, freshmen losing twenty-nine per cent. from illness; sophomores, twenty-eight; juniors, twenty-three; seniors, nineteen; or a decrease of disability of about ten per cent. The number of Amherst students from whom these data were obtained is 2106, and the average 21.1 years. The period of their observation was four years, and their average per cent. of good health was seventy-five per cent. of the whole number.

RICKETS IN ANIMALS.

AN opportunity has fallen to Mr. J. B. Sutton to make the post-mortem examinations of wild animals dying in the Zoölogical Gardens, in Regent's Park, and the result has been an article on Rickets in Wild Animals. (*Journ. Anat. and Phys.*, July, 1884.)

Rickets appear to be a very common cause of death among wild animals in the captive state, equaling in the Zoölogical Garden fifty per cent. of all kept in confinement, and Mr. Sutton has carefully recorded the clinical and pathological aspects of the disease. He describes the disease in three forms: (1) rickets of infancy, (2) of puberty, and (3) of maturity.

In the (1) rickets of infancy the clinical aspects of the disease have been principally followed out in

monkeys. The animal becomes less lively than usual; he grovels about on the floor, and if pushed shrieks with pain; this is soon followed by impairment of the power of locomotion, finally ending in paraplegia, accompanied by priapism, incontinence of urine and fæces. The disease develops with great rapidity, and a rickety monkey that develops a cough soon succumbs.

The observations on (2) rickets of puberty ("late rickets" in the human subject) were conducted chiefly on baboons, bears, tigers, and lions. The symptoms are very few, but very definite. The animal shows signs of paralysis and defective dentition; gradually it becomes completely paraplegic, and is killed on this account.

The (3) rickets of maturity are rarest of all, the characteristic features of the disease being deformity, paraplegia, loss of teeth, and fractures of the bones of the limbs.

The causes of rickets are considered to be an unsuitable diet, frequent pregnancies, want of proper exercise, and what is termed "in-and-in breeding."

Mr. Sutton draws up the following table to indicate the distribution of the various pathological lesions according to age: —

	Infancy.	Puberty.	Maturity.
Skull.	Soft and somewhat thickened at the vault. Exterior may present a worm-eaten appearance. The base often presents tabetic patches.	Vault thickened.	Softened generally, and eroded.
Vertebræ.	Spongy and soft, encroach on the neural canal, causing paraplegia.	Present bulging at the disks and epiphyseal plates. Paraplegia.	Soft, spongy, and vascular. Paraplegia.
Thorax.	Deformed and beaded. Infractions of ribs.	Beaded. Infractions of ribs.	Nil.
Long Bones.	Soft, curved, with large epiphyses. Spongioid tissue reaches its maximum.	Fibrous tissue in a thin layer at the epiphyseal line Spongioid tissue at a minimum.	May be often soft and curved, or the compact tissue exceedingly thin and brittle.
Teeth	Temporary set. Normal.	Permanent set, late in appearing.	Fall out prematurely, due to absorption of sockets.

This is an instance of careful pathological study in animals, which is not without its direct application to the human species. We have often expressed our belief that such study of comparative pathology was one of the ways by which our knowledge of human ills might be best increased. The existence of a chance specimen of rickets in a domestic animal was made, not long ago, in the pages of the JOURNAL, the basis of an argument against the identity of rickets and syphilis. One result of Mr. Sutton's autopsies will be to greatly strengthen such an argument. Such study bids fair also to throw even more definite light upon the ætiology of the disease. And we believe the time will come when not only the results of pathological processes in animals will be studied for the benefit of humanity, but when the observation of the course of these processes will be used as a means of clinical instruction.

— The return of a hernia, irreducible for many years, is reported as having occurred after a fit of sneezing.

TUBERCULOSIS OF THE FEMALE GENITAL ORGANS.

IN the Transactions of the Société Anatomique[1] appears an account of the case of a woman, aged fifty-one, whose symptoms at first suggested typhoid fever, but in the absence of epistaxis, rose spots, ilio-cæcal gurgling, etc., and after the detection of disease at the apices of the lungs, the diagnosis of tuberculosis of the intestine was made. The course of the disease was rapid, and death ensued. At the autopsy tuberculosis of the lungs was observed, with cheesy softening, and cavities at the left apex. No tubercles were discovered in heart, spleen, kidneys, or liver. The latter organ was fatty. The mesentery showed miliary granulations, with swelling of the lymphatic glands. The intestine had whitish spots on its serous surface, elevating the peritonæum. These were scattered all over the small intestine and the ascending colon, especially abundant at the cæcum, where they became confluent. On opening the intestine it was found that each of these external spots corresponded to an ulceration of the mucous membrane internally, the ulcers being irregular, scalloped, rather deep, with sharp edges and sanious bases. Here and there a Peyer's patch was found ulcerated.

The uterus and its adnexa showed nothing externally, except an ulceration at the left of the cervix, extending through the mucous membrane. The vagina was perfectly healthy. The uterine cavity had preserved its physiological dimensions, and was quite filled with a whitish caseous substance. The mucous membrane was much altered, channeled with winding cavities of small dimensions, which contained the same substance, and discharged it into the uterus. The Fallopian tubes were much increased in volume, having at their free extremity a diameter equal to that of a quill. They were very tortuous, their calibre filled with the same cheesy substance as the uterus, and their mucous membrane presenting the same appearance. The broad ligaments had old adhesions, but no tuberculous lesions. The ovaries were both in a state of caseous degeneration. The peritonæum over them presented whitish salient spots like those of the intestine.

The age of the woman was such that, menstruation having ceased, nothing had called attention to the diseased state of the genital organs.

MEDICAL NOTES.

— Dr. Chervin has, according to *Science*, been studying with reference to disabilities which are developed by the annual conscription. The period chosen covered twenty years. After those cases of feeble constitution, evidently unfit for military duty, the most frequent disability was dental caries, after which followed hernia, etc. In considering the Department as a whole the average number of conscripts

[1] Le Progrès Medical, August 16, 1884.

rejected on this account was fifteen per cent., but in considering the separate cantons it was shown that they vary greatly in this regard, the least average being eight per cent., and the highest nearly twenty-four per cent. In seeking a cause for this singular difference, that sometimes alluded to, the drinking of sour Norman cider, was considered to have little real influence. The question of race was believed to be more important. So far as form and height are concerned, the tables for twenty years showed two physical groups or races, — the smaller in the west, the larger in the east, especially about Dieppe and Neufchatel. The taller race is much more subject to dental caries than the other, and this is confirmed by testimony from other departments. Baldness prevails to such an extent that two per cent. of the recruits examined were exempt on that account at the early age of twenty. Some connection appears to exist between this deficiency and decay of the teeth.

— The *Medical Times and Gazette* quotes from *Lo Sperimentale*, December, some observations on the irregularity of the pupil in the insane by Dr. Mosso, of the Turin Manicomia. He describes the results of the examination he has made of the pupils in three hundred insane and one hundred sane persons. Since Baillarger called attention, in 1851, to the frequency and diagnostic value of inequality of the pupils in general paralysis of the insane, other observers have shown that the same circumstance is observable in many other affections of the nervous centres, but in the present paper Dr. Mosso wishes to draw attention to the frequency of irregular shape of the pupil in insanity, and its occasional occurrence in the sane. Of the three hundred insane the pupil was found rotund or sub-rotund in sixty per cent.; oval in seven per cent.; irregular in twenty-five per cent.; and very irregular in three per cent. In the one hundred sane persons it was found to be irregular in nine. The general conclusions drawn are: (1.) That in the insane pupillary irregularity is of frequent occurrence, and is usually bilateral. (2.) In diseases of the nervous centres irregularity and inequality of the pupils have the same pathological significance, irregularity being, in fact, the first stage of inequality. Dr. Mosso only puts forward these observations tentatively, and asks for their corroboration by other inquirers.

— A telegram to the *London Times* from Philadelphia states: "The defunct Medical University of Philadelphia, which has caused great annoyance and trouble by selling bogus diplomas, has reappeared. The English consul at Philadelphia, Mr. Clipperton, states that he is in receipt of letters from various parts of Great Britain asking for information about the standing of the college, and to what extent its diplomas are accepted. The government here has done all in its power to stop the illegal traffic in diplomas by canceling the charter of the college and closing it. If impostors are still committing fraud upon the public through agencies in England they should be prosecuted by the British authorities."

— From a foreign exchange we learn, remarks the *Medical Press*, that Professor Hegar has recently read a paper at Freiberg in which he advocates stretching the spinal cord. Our readers will be glad to hear that the operation does not consist in opening the spinal canal and directly stretching the spinal medulla. But Dr. Hegar has found that when the spine is very much bent the cord is actually lengthened. His mode of procedure is to place the patient on his back, and then, with the knees kept carefully straight, the lower limbs are bent up towards the chin as far as possible. In this way the great sciatic nerves are put on the stretch, and this, as well as the over-bending of the spine, stretches the lower end of the cord. The cases for which Dr. Hegar recommends this treatment are those of women who suffer from pelvic pain, and of nervous phenomena referable to the branches springing from the lumbar enlargement of the cord. Already the treatment has been employed in a few instances, and, it is stated, with success.

— The following words will be read with interest by all prayerful souls who are looking for the millennium of medicine. The remarks are from an article upon the Microscope in Analysis in the *Scientific American* of August 30, 1884: "The student of medicine is to-day enabled to unravel, before the potent glance of the perfected microscope, the deepest mysteries of the medicinal plant, flower, herb, or root. The nature, virtues, attributes, etc., of these can be studied at leisure, and gazed upon with an eye that magnifies from a few hundred to thousands of diameters."

— A new sponge and wound-pad has, we learn from the *British Medical Journal*, been manufactured for Mr. Sampson Gamgee as the result of a suggestion made by Sir T. Spencer Wells. It differs from the ordinary sponge inasmuch as it is a powerful absorbent in its dry state, and need not be previously wetted. Its absorbing power is said to be equal to fully sixteen times its own weight. It consists of concentric layers of absorbent cotton and cocoa-nut, or like fibre, within a covering of absorbent gauze. Its antisepticity is secured by placing in the centre a thin and easily friable capsule containing the antiseptic of any kind desired, eucalyptia or thymol, carbolic acid, bichloride of mercury, etc. An antiseptic may thus be inclosed within absorbent materials, and preserved intact for weeks and months together, if necessary, until required for use. All that is required is a sharp squeeze of the sponge or pad just before using it; and by subsequent burning all fear of sponge-infection is avoided and becomes impossible.

NEW YORK.

— The first meeting this season of the Society of Medical Jurisprudence and State Medicine was held Thursday evening, September 11th, when two papers read at previous meetings were discussed. The first was one on the Fillmore Will Case, by Dr. L. C. Gray, and the second one was on the Dwight Insurance Case, by Dr. J. G. Kiernan, now Superintendent of the Chicago Lunatic Asylum.

— The Academy of Medicine has lost a legacy of $5000 by its action last autumn in rescinding the Flint resolutions requiring the committee on admissions to recommend for membership only such candidates as supported the National Code of Ethics, which the Constitution distinctly declares to be the Code of the Academy. The late Corresponding Secretary, Dr. John G. Adams, left the Academy $5000 in his will; but after the action referred to added a codicil revoking the legacy and devoting the amount to various charities. Among the bequests in the will is the endowment of a free bed in the Presbyterian Hospital.

— During the first week of September the joint water commission of Newark and Jersey City held a meeting in reference to the pollution of the Passaic River by the sewage of Paterson and Passaic City.

Correspondence.

HOUSE OFFICERS OF THE MASSACHUSETTS GENERAL HOSPITAL DURING ELEVEN YEARS PAST.

Massachusetts General Hospital,
Boston, *August* 11, 1884.

Mr. Editor, — I herewith send a list of the house officers of the Massachusetts General Hospital for the past eleven years, believing that the more carefully it is examined the more clearly it will appear to all unprejudiced minds that the appointments have been made from no motives of nepotism or favoritism, but with the simple purpose of getting the best available men for the service of the hospital. Whether this object has been obtained with a fair degree of success, or whether better men would have been selected by strict adherence to the results of a competitive examination, is a matter of individual opinion.

Miscellany.

ERYTHROXYLON COCA.

Dr. Squibb writes[1] regarding this drug: The condition of the principal markets of the world for coca for the past six months has been exceptionally bad. That is, whether good coca was sought for in the ports of Central and South America, or in London, Hamburg, or New York, the search, even without limitation in price, was almost invariably unsuccessful. Not that the drug, independent of quality, was scarce, for hundreds of bales were accessible at all times, but the quality was so poor as to be quite unfit for use. The samples, instead of being green and fragrant, were brown and odorless, or musty and disagreeable, at once condemning the lots they represented, to the most casual observation, and yet the price was high enough to have represented a good article. The best that could be done, by the most careful buyers, was to accept occasional parcels, the best of which were of very inferior quality, and therefore unfit for medicinal uses, and these at very high prices. Coca is well known to be a very sensitive and perishable drug, only fit for its somewhat equivocal uses when fresh and green and well cared for in packing and transportation. Very much like tea in this and other respects, it should be packed and transported with the same care and pains, in leaded chests, or in some equivalent package. It is very well known that tea, if managed, transported, handled, and sold as coca is, would be nearly or quite worthless, and therefore coca, managed as the great mass of it is, must be nearly all of it comparatively worthless. If used as tea is, this would probably soon appear, but when used as a medicine, which has been highly extolled and well advertised, it seems to go on equally well whether of good or bad quality. It is pretty safe to say that nineteen twentieths of the coca seen in the United States market within the past two years must be almost inert and valueless, yet all is sold and used, and its reputation as a therapeutic agent is pretty well kept up. At least many thousands of pounds of the brown ill-smelling leaf, and of preparations made from it, are annually sold. And worse than this, considerable quantities of a handsome looking green leaf, well put up, and well taken care of, have been sold and used as coca, when wanting in nearly all its characteristics.

The writer for more than a year past has seen but one or two small lots of moderately good coca, and in common with other buyers has been obliged to buy the best that could be found to keep up his supply of the fluid extract. Almost every purchase has been made on mental protest, and he has been ashamed of every pound of fluid extract sent out, from the knowledge that it was of poor quality; and there seems to be no more prospect of a supply of better quality than there was this time last year, because so long as an inferior quality sells in such enormous quantities at good prices the demands of trade are satisfied.

Under this condition of the markets the writer has finally decided to give up making a fluid extract of

[1] Ephemeris, July, 1884.

coca, and has left it off his list, adopting a fluid extract of tea instead, as a superior substitute, for those who may choose to use it, and regrets that this course was not taken a year ago.

The character of coca as a therapeutic agent is discussed by Dr. Squibb, and the discrepancy referred to between the results obtained by Sir Robert Christison and those by Mr. Dowdeswell in the physiological laboratory of University College. This discrepancy can be accounted for only by supposing the two observers to have used a different article. Mr. Dowdeswell claims that the annual consumption of 40,000,000 pounds of this comparatively inert substance at a cost of $10,000,000 is an example of one of the large economic blunders of the age.

Dr. Squibb's own remarks upon the power of coca were based upon the premise that the same power in tea, coffee, guarana, etc., which refreshes, recuperates, and sustains in the condition which needs or requires such effects, also counteracts the tendency to sleep or produces wakefulness when a tendency to sleep exists, and, therefore, if a tendency or disposition to sleep could be prevented by these agents this tendency might be used as a measure of their effects when used in varying quantities, and thus measure the agents against each other for dose or quantitative effect. In this way the proposition is to first measure coca against tea, then coffee against guarana, and finally to compare the four agents, using pure caffeine as a kind of standard to measure by.

An opportunity for such trials occurred in a healthy individual, sixty-five years old, not habituated to the use of either tea, coffee, tobacco, or any other narcotic substances, of good physical condition and regular habits, and not very susceptible or sensitive to the action of nervines or so-called anti-spasmodics. Quantities of preparations of valerian, asafœtida, compound spirit of ether, etc., which would yield a prompt effect upon many individuals, seem to have little or no effect upon him, nor do moderate quantities of wines or spirits stimulate him. That is to say, he has not a very impressible nervous organization, is not imaginative, nor very liable to accept results on insufficient or partial evidence.

Fully occupied with work, both physical and mental in due proportion, for more than ten hours every secular day, when evening comes he finds himself unable to read long on account of a drowsiness, supposed to be of a purely physiological character. With a full breakfast at about 7.30, a full dinner at about 2.30, and a light evening meal about seven, and no stimulants or tea or coffee at any time, he finds, as a matter of not invariable but general habit, that by half-past eight drowsiness becomes so dominant that it becomes almost impossible, and generally impracticable, to avoid falling asleep in his chair while attempting to read, even though ordinary conversation be carried on around him.

The first trial to combat or prevent this drowsiness was made with caffeine. The first specimen used was a very beautiful article made by Merck, of Darmstadt, and after that by pure specimens made for the purpose, the two kinds being found identical in effect.

Commencing with a one-grain dose at about 6.30 P. M., on alternate evenings, leaving the intermediate evenings in order to be sure that the nightly tendency still persisted, and increasing by half a grain each alternate evening, no very definite effect was perceived until the dose reached two and one half grains, and this dose simply rendered the tendency to sleep resistible by effort. After an interval of three evenings, with the tendency to sleep recurring with somewhat varying force each evening, a dose of three grains was taken, the maximum single dose of the German Pharmacopœia. This gave a comfortable evening of restedness, without sleep, or any very strong tendency to it, until ten o'clock. Without anything to counteract sleep the rule was to read with difficulty by nine, without much comprehension by a quarter-past nine, and either be asleep or go to bed by half-past nine. The three-grain dose of caffeine repeatedly obviated all this discomfort up to ten o'clock, but did not prevent the habitual, prompt, and sound sleep from the time of going to bed till morning.

To produce a corresponding effect three fluid drachms of a good preparation of fluid extract of coca were necessary. An equivalent amount of the coca preparation assayed .45 grain of cocaine. If, then, three grains of caffeine equals in physiological or therapeutical effect .45 grain of cocaine, it follows that cocaine is about 6.5 times more effective than caffeine, but it also follows that the coca accessible, and even the very best coca, contains very much less of its alkaloid than those articles which yield caffeine do of that principle.

A BUSY LIFE.

A CORRESPONDENT of the *Canadian Medical Journal* for July gives an interesting glimpse of a many-sided man — the distinguished professor of pathology at Berlin, Professor Virchow. After a short sketch of his life, the different chairs of instruction he has held, the noted men who have been his pupils and assistants, including Klebs, Recklinghausen, Rindfleish, the recently-dead Cohnheim, Liebreich, Hoppe-Seiler, Orth, Ponfick, etc., we are shown how after forty years of teaching he still works: —

"For the first three or four Mondays of the semester, from 7.30 to 10 A. M., he performs an autopsy before the class, giving detailed directions as to methods and the proper modes of observation. On Wednesday and Saturday are held the famous demonstration courses on morbid anatomy, in which the material for the week, often ten or fifteen cases on each occasion, is brought before the students. The time occupied is at least two and a half hours, the first half of which is taken up by some special subject, the pathology of which is well illustrated by the specimens at hand. At eleven A. M. he gives each day a lecture on special pathology. Politics and anthropology now absorb the greater part of his time. He is a member of the German Parliament and of the Prussian House of Representatives; and I noticed a day or so ago in one of the daily papers that Virchow had spoken in one of these thirty-eight times during the session. It need scarcely be stated that he is an advanced Liberal. He is also a member of the City Council — not an idle one either, as the copious literature of the "canalization" (drainage) system of the city can testify. His archæological and anthropological studies are most extensive, and it is upon these subjects that he now chiefly writes. When one turns to the Index of the Berlin Archæological or Anthropological Societies, the figures after his name stand thick and deep, just as they do in a similar index of medical subjects. He has been collaborator with Dr. Schliemann in several of the important works issued

on Trojan antiquities. His collection of skulls and skeletons of different races, one of the most important in Europe, will doubtless find an appropriate place in the new Archæological Museum erected by the government. There are those who grudge him the time he spends on politics and his favorite studies, but surely he has earned a repose from active pathological work, and may well leave section cutting and bacteria staining to the smaller fry; and when we consider that in addition to the classes above mentioned he is President of the Berlin Medical Society, and edits his *Archiv*, now a large monthly journal, it can scarcely be said that he neglects professional duties. On all questions of general, medical, and scientific interest his utterances are not infrequent, and display a judicious conservatism — as witness his sound position regarding the Darwinian theory as opposed to the vagaries of Haeckel. It is satisfactory to note that the attack of gouty nephritis of some eighteen months ago appears to have left no trace. Aged, of course, he is (he is now sixty-three), but there is still a vigor and sprightliness in the wiry frame which bespeak years of continued activity."

A CASE OF ACUTF POL'OMYELITIS IN THE ADULT.

Dr. John Van Duyn, of Syracuse, N. Y., reports, in the *Archives of Medicine*, August, 1884, a case which is of interest as presenting a nearly typical record of this disease, as well as showing the apparent cause of the malady with unusual distinctness.

F. D., a clothier's clerk, twenty-three years old, of average height and good muscular development. Had worked on a farm during summers until 1880, which year he spent at school. Early in 1881 he entered a clothing store as clerk, but in the following November he had malarial fever, and in February, 1882, had a moderately severe attack of typhoid fever. From the time of his recovery, in early spring, until the following October, he worked on a farm, and then resumed his position as clerk. Had never had venereal disease, and had never been intemperate in the use of alcohol.

August 24, 1883, he walked nine miles, arriving at his destination at two o'clock the next morning; went to bed at three o'clock, and slept six hours. At noon he engaged with others in "putting" a stone, which weighed nearly forty pounds, and in jumping. The stone was "put" from the shoulder by the right arm forward, and thrown by both arms over the head backward. This contest was most violent, and lasted two hours. Then he ate a hearty dinner. At 4.30 P. M. he walked over three miles, then rode in a stage two miles, and in the cars ten miles, after which he walked with friends in the city, and finally went to bed at eleven o'clock. The next day he felt some soreness, which, in a day or two, entirely passed away. Until the end of the two weeks following his life was as it had been before. By his exertion he did not become overheated, was not chilly, nor did he take cold. On September 7th, when he woke in the morning, he felt severe pain between the shoulders, equal in intensity on both sides of the spinal column, which was greatly increased by turning the head to either side. He went to work, but during the day he felt chilly, and his face was very red. In the afternoon the right hand began to lose its grasp, so that he could hardly hold the pencil in making sale-tickets. The power to use this hand grew gradually less, until, three days later, it disappeared entirely. That evening he rode ten miles by rail. He could not sleep because of headache, chills, and nausea. The soreness became universal. The second day he got up, could raise the right hand to his face, but could not button his clothes with it. He walked to see the village doctor, but found the strength of his legs failing to the extent that, in the afternoon, when he rode home, three miles distant, he could with difficulty get into and out of the wagon. Went to bed at night and "took a sweat." The third day felt sick and sore, but could get up, and even went out of the house. When he tried to put on his hat with his left hand, the right being powerless, he found it impossible, and with difficulty only could he lift this hand to the latch of the door. After he had gone to bed at night he found he could not raise either elbow from the bed. From this time on he was confined to the bed. He suffered from general soreness. To breathe gave him pain, and he could not lie on either side because of the pain which the pressure on the chest gave him. The whole body, excepting the head and neck, was so sensitive that suffering was caused by the gentlest touch. During the following three or four days paralysis of motion became general in the extremities, but not affecting the head, neck, thorax, and the left fore-arm and hand. Could not raise his heels from the bed, but, while on his side, could partially flex the thighs on the abdomen. Constipation became severe, but the bladder was unaffected. During this time the temperature was twice observed and recorded. On the fourth day it rose to 102° F.; a few days later to 101° F. After the tenth day improvement began to be manifest, and continued until the end of the second week, when he could get into a chair, but could not stand, nor could he raise his feet from the floor. The soreness had receded to the shoulders. At the end of the third week could walk with assistance, but could not lift the feet higher than enough to prevent dragging. Constipation continued, and did not disappear until two months later. The right arm was powerless. The left arm was recovering strength rapidly. This arm had not been affected below the elbow. At the end of the fourth week he could walk alone, the right leg having regained considerable strength, but the left leg could as yet be moved only with difficulty. At this time he began to feed himself again by using the left hand after the elbow had been rested on the table. Throughout there had been no abnormal sensations, no numbness. During these four weeks he lost sixty pounds in weight.

Examination, January 12, 1884. Complete loss of voluntary motion in, and great atrophy of, all the muscles supplied by the right brachial plexus, exceptin those supplied by the fifth and sixth cervical roots The right hand, with extreme atrophy in all parts, was *en griffe*. The muscles of this extremity, including those of the shoulder, were unaffected by faradism, but all, with the exception of those in the hand, reacted to strong galvanism. On the left side the supraspinatus and infra-spinatus were greatly atrophied, the pectoral muscles less so, while all contracted under faradism. The elbow could with greatest difficulty be raised to the level of the shoulder. Below the shoulder the left arm was normal. Power to raise either knee was diminished. The left anterior tibial was not under control of the will, and was atrophied, but reacted to strong faradism. Because of the loss of this muscle the foot falls in extension when raised.

To the present time, May 16th, treatment by electricity has been almost daily. All the muscles of the right upper extremity contract under galvanism, with the formula CCC. > ACC., while the brachialis anticus, biceps, sup. longus, and pectorales major and minor contract under faradism. The pectoral muscles, biceps, and anterior brachial show decided contractions by the will. The nutrition of these muscles under the influence of the will so far exceeds that of the others that their growth causes them to stand out in marked contrast with the surrounding atrophy. The will has control of all the affected muscles of the left shoulder and of the left anterior tibial.

The writer remarks that should the gymnastic violence be conceded as the cause, than which no other is apparent, then interest must attach itself to the length of time which intervened between the cause and the outbreak of the disease, and to the fact that while both extremities, upper and lower, were affected during the fever, the muscles which remained paralyzed and atrophied were those most violently exercised, and the severity of the results and their permanency are in direct ratio with the use of the muscles.

CHRONIC ILEO-COLITIS AND LARYNGISMUS STRIDULUS.

DR. ROBERTS BARTHOLOW, in a clinical lecture, made the following remarks upon a case showing the above complication: The child before you was shown you some time ago, suffering with chronic ileo-colitis. The disease had been extremely persistent and severe, but under a properly regulated diet and the use of tincture of iodine and carbolic acid, the so-called carbolate of iodine, — a half a drop of each being taken three times a day, — there has been rapid improvement, and now the symptoms have disappeared, notwithstanding that the instructions in regard to the regulation of the diet have been imperfectly obeyed. You will remember that I insisted upon a change in the diet as of the first importance in the treatment of this case.

I hope that you will observe the character of the cough which the child has. It has frequently occurred ever since the existence of the ileo-colitis. Every time the child takes cold it has this hard, ringing cough which you now hear, and which is termed a "croupy cough." I have on several occasions insisted that this phrase is a misnomer. It is called croupy simply because it has the loud, ringing, metallic character which is associated with the cough of spasmodic croup. This is not the true croupy cough. The cough of exudative laryngitis is husky in addition to being ringing and metallic. The cough which this child presents is significant of laryngismus stridulus; that is, an affection of the larynx in which the muscles are thrown into a state of spasm. A child who during the day has been exposed to the cold, or who in the evening has eaten heartily of indigestible food, wakes up in the night with an attack of so-called croup. This is really an example of laryngismus stridulus, or spasm of the muscles of the larynx. In the case I have supposed there are two factors: the child takes cold, or it has an irritation of the gastro-intestinal mucous membrane. We can here apply with great certainty our physiological knowledge. The mechanism is very obvious. The pneumogastric nerve which supplies the mucous membrane of the fauces, and the gastro-intestinal mucous membrane in part, also has branches going to the larynx. This nerve is both motor and sensory in function. All the muscles of the larynx, with the exception of the crico-thyroid, are supplied by the inferior laryngeal nerve, while the superior laryngeal nerve is distributed to the mucous membrane and the crico-thyroid muscle. Now we have the terms of the problem. Irritation of the peripheral distribution of the pneumogastric nerve is referred to its motor branches, and the muscles of the larynx are thrown into a state of spasm. It would be a great mistake to confound this condition with true croup.

ACUTE INTUSSUSCEPTION IN AN INFANT EIGHTEEN WEEKS OLD.

A CASE of acute intussusception remarkable for the favorable result in so young a child and for the clearness of the diagnosis is reported in the *Lancet* (August 30th) by Dr. Collier. The infant had been suckled from birth, but as the mother did not have sufficient milk she supplemented this diet with small quantities of bread soaked in water and sweetened with sugar. For a week before he was seen the child had vomited a little milk after each meal. The dejecta had been constipated, slimy, and offensive. On February 15th, whilst lying asleep in his mother's arms, he suddenly became convulsed and appeared in great pain, screaming loudly and struggling, so that it was with difficulty that he could be held. After the fit had lasted a few minutes the struggling gave place to violent straining, "as if he was trying to relieve himself," and during these efforts a large quantity of gas was discharged per anum. On the diaper being inspected it was found to be soaked with bright blood and slime, but did not contain any fæcal matter. He now appeared more calm, and after a short time took the breast, but almost immediately afterwards became very sick, bringing up a large quantity of milky fluid. Since then he had mostly been quiet, crying and straining only by "fits and starts." He had taken small quantities of milk and water from a teaspoon, but nearly always returned them immediately. No natural action of the bowels had occurred since an hour before the onset of the attack, although the diapers were several times found stained with "bright watery blood." Urine was passed more frequently, but in smaller quantities than usual.

On examination the following day at four P. M., the condition of the child was found to be as follows: He was well nourished, but much collapsed, with pale face and pinched, drawn features; pulse 100, feeble and irregular; respiration 30, shallow; skin cold and perspiring; temperature 100.5° F., taken in the rectum. There was much distention of the abdomen, and percussion yielded a tympanitic note, except where the right inguinal and hypogastric regions were occupied by an elongated swelling, which ran in a direction upwards and inwards and could plainly be seen and felt. Pressure over this tumor gave rise to crying and struggling on the part of the infant. On account of his tender age it was not considered advisable to extend the examination to an exploration of the rectum. Three blood-soiled diapers were shown by the mother, and one of them, said to be in use at the onset of the at-

tack, contained about two ounces of blood and mucus.

The treatment for five or six hours consisted of hot fomentations applied to the abdomen, and a mixture containing tincture of belladonna, chloric ether, and sal volatile in appropriate doses every two hours. Brandy was also given. At nine P. M., the condition remaining substantially the same, it was decided to anæsthetize, and attempt to dislodge the prolapsed portion of bowel by injecting water. After chloroform had been inhaled some few seconds, and before insensibility was produced, the patient became violently sick, ejecting about half a pint of pale-yellow fluid, having a strong fæcal odor. The pulse at this moment became scarcely perceptible, and the child appeared in the gravest danger, but on chloroform being suspended and ammonia applied to the nostrils the pulse returned, and remained fairly strong throughout the remaining stages of anæsthesia. The fingers of one hand being kept in contact with the sausage-shaped tumor described above, warm water was slowly injected into the rectum by means of a Higginson's enema syringe, care being taken to prevent its return by the side of the nozzle. When about twenty ounces had been injected a sense of the tumor slipping away was plainly perceptible to the fingers in contact with the abdomen. By the time some thirty-five to forty ounces had been injected the tumor had entirely disappeared, and the most careful examination failed to detect it. The patient was now wrapped in warm blankets, and the injected fluid allowed to drain off. During returning consciousness the child once more vomited freely, bringing up fluid of the same color, and possessing the same strong fæcal odor as before. Ten drops of brandy in a teaspoonful of ice-cold water were subsequently administered and retained, and the child afterwards manifested an inclination to sleep. The hot fomentations were again ordered to be applied to the abdomen, and the belladonna mixture to be given every two hours. At twelve P. M. a large quantity of water was found to have been passed per anum. The child appeared more comfortable, and was sleeping calmly. He had not evinced a desire for milk when placed to the breast. On the diapers being changed about two tablespoonfuls of dark-yellow fæcal matter were found to have been passed. The fomentations were ordered to be continued to the abdomen, and the mixture given every four hours.

During the night the child took the breast twice, and had another natural action of the bowels at six o'clock the following morning. From this time the patient made an uninterrupted recovery.

DISSEMINATED SCLEROSIS.

THE study of a case of disseminated sclerosis which, in its clinical features, closely simulated lateral amytrophic sclerosis, has given M. Déjérine[1] the opportunity of making some interesting and valuable remarks on the pathology of scleroses in general. The case which forms the starting point of the paper was that of a woman, aged forty-six years, who had had for fourteen months atrophic paralysis, with contracture of all four limbs. The disease commenced in the legs, spreading thence to the arms, and ultimately to the lower part of the face; the paralysis of the limbs became absolute, and the atrophy extreme; it was throughout symmetrical. An interesting feature of the case was the high degree of contracture which was present; so great was it that it could not be altogether overcome by the employment of force; the tendon reflexes were highly exaggerated. The general and special sensibility was unimpaired; but towards the end there were some symptoms of labio-glossal paralysis. At the autopsy it was found to be a case of disseminated and not of lateral amyotrophic sclerosis. Spinal and cerebral scleroses, M. Déjérine goes on to say, may be and ought to be divided into primary when the neuroglia is affected from the outset by the irritative process, and secondary when it is only the result of the nerve disorder. In disseminated sclerosis the affection of the neuroglia is primary, as is shown by the fact that the nerve tubes and axis cylinders disappear very slowly from gradual compression by the contracting neuroglia. In tabes dorsalis the contrary is seen; for the axis cylinder disappears before the neuroglia has commenced to proliferate. Disseminated sclerosis, then, and probably all forms of non-systematic sclerosis have a vascular origin; whereas, in systematic sclerosis, the vascular lesions which are present are secondary. Thus, in a case of hemiplegia, fatal just when rigidity was setting in, the vessels of the pyramidal fasciculus were already found to be undergoing endo- and peri-arteritis, and their lymph sheaths were distended with corpuscles; but the nerve tubes showed a much more advanced state of degeneration, the axis cylinders having already disappeared, and the neuroglia showing traces of irritation at a point far removed from the vessels, contrary to what takes place in non-systematic sclerosis. The vascular origin of the patches in the latter explains both their scattered distribution and the absence of any tendency to spread in a systematic manner.

HYDRAMNION IN EXTRA-UTERINE PREGNANCY.

AN interesting case of this kind is reported by Dr. R. Teuffel, of Chemnitz, in a recent number of the *Archiv für Gynäkologie*. It is important as exemplifying a rare source of error in diagnosis. The patient was thirty-six, and her last child had been born fourteen years previously. Menstruation stopped in March, 1881, and the usual symptoms of pregnancy were noticed. In August, 1881, the patient suffered from severe and long-continued abdominal pain, and was medically treated for inflammation of the bowels. September 25, 1881, labor-like pains came on, with hæmorrhage and the expulsion of a membrane, this latter being seen only by a midwife. Birth was daily expected, but did not follow, and fœtal movements were still felt in October and November, after which they ceased, and the size of the belly began to slightly diminish. In 1882 the abdomen began to increase again; she felt well, and in March, 1882, menstruation reappeared. When she came under treatment she was wasted, sleepless, suffered pain, but was not feverish. The circumference of the belly was 116 centimetres (forty-six inches); it was dull, with resonance in the flanks, fluctuating, with solid masses here and there to be felt. A firm, rounded swelling occupied the pelvis, pushing the uterus upward, forward, and to the right. There was no œdema of legs or other parts. The case was diagnosticated as one of ovarian cyst, and an ex-

ploratory puncture was made. The fluid withdrawn gave a sediment, on standing, in which striated muscular fibre was identified. Feverish symptoms followed the puncture, with pain, diarrhœa, and vomiting, and in ten days the patient died. On autopsy the cyst was found to contain a full-term, macerated child and several litres of amniotic fluid. There was neither effused blood nor signs of peritonitis, so that the immediate cause of death remained a mystery.[1]

PROF. R. E. ROGERS, M. D.

PROF. ROBERT EMPIE ROGERS, of Jefferson Medical College, Philadelphia, died on Saturday, September 6th, at the age of seventy. He was born in Baltimore in 1814, and graduated from the Medical Department of the University of Pennsylvania in 1836. He was for eight years Professor of Chemistry in the University of Pennsylvania, and subsequently Professor of Chemistry in the Medical Department of the University of Pennsylvania. In 1877 he accepted the chair of Chemistry in Jefferson Medical College, the duties of which position he only recently ceased to discharge. He was an excellent teacher and a lecturer, much liked and appreciated both by his colleagues and students.

DR. RIGGIN BUCKLER.

DR. RIGGIN BUCKLER, of Baltimore, who died recently (August 31st) at Narragansett Pier, was a graduate of Harvard College and of the Medical School of the University of Maryland. After graduating in medicine he studied four years in Paris giving special attention to physiological chemistry.

He was popular and successful as a practitioner in Baltimore, continuing the medical reputation attached to the name since the active days of his father and uncle, Drs. John and Thomas Buckler. He was twice Surgeon-General of Maryland.

OBITUARY. DR. JULIUS COHNHEIM.

PROFESSOR JULIUS COHNHEIM, of Leipsic, one of the foremost of pathological investigators, died on the 14th ult., at the early age of forty-five, from the chronic affection (renal disease) from which he had been so long a sufferer. After having studied medicine from 1856 to 1860 at Berlin, Würzburg, Greifswald, and Prague, he commenced practice at Berlin. In 1864 he served under Rudolf Virchow as assistant in the Pathological Institute in Berlin. It was with much appropriateness that the announcement of his death was made by his old master, Virchow, before the Section of Pathology in the closing days of the Copenhagen Congress. In 1868 he was professor of the same department in the Medical School of Kiel, and four years later he was transferred to the chair of Pathology in the University of Breslau, where his prælections attracted so much attention that on the first vacancy he was called to fill the professorship at Leipsic, which became immediately associated with his best work. His name will live chiefly for his signal contributions to the doctrine of inflammation, his experimental proofs — by vivisection mainly — having been universally admired for their careful exclusion of every source of fallacy. He showed that in all inflammatory processes, without exception, the greatest part of the pus-corpuscles consist of white blood corpuscles that have passed through the walls of the veins and capillaries. Till this induction was arrived at Virchow's view was the prevalent one, — namely, that the pus corpuscles are connective-tissue corpuscles transformed through cell-cleavage. "Without blood-vessels no inflammation is possible," was Cohnheim's great thesis, a doctrine which had been foreshadowed by others, notably Waller in 1848, but waited for its full scientific establishment for Cohnheim.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, UNITED STATES ARMY, FROM SEPTEMBER 6, 1884, TO SEPTEMBER 12, 1884.

GREENLEAF, CHARLES R., major and surgeon. To conduct a detachment of recruits to the Department of the Columbia, and upon completion of this duty rejoin his station, Columbus Barracks, Ohio. S. O. 210, A. G. O., September 6, 1884.

GORGAS, W. C., first lieutenant and assistant surgeon. Assigned to duty at Fort Randall, D. T. S. O. 98, Department of Dakota, September 5, 1884.

EGAN, P. R., first lieutenant and assistant surgeon. When relieved by Assistant Surgeon Fisher to report at Fort Lowell, A. T., for duty as post surgeon. S. O. 82, Department of Arizona, September 2, 1884.

FISHER, W. W. R., first lieutenant and assistant surgeon. Assigned to duty at Fort Apache, A. T., relieving Assistant Surgeon Egan. S. O. 82, C. S., Department of Arizona.

EWING, CHARLES B., first lieutenant and assistant surgeon. Assigned to duty, as post surgeon, at Fort Stanton, N. Mex. S. O. 177, Department of the Missouri, September 6, 1884.

MCCAW, W. D., first lieutenant and assistant surgeon (recently appointed). To report in person to the commanding general, Department of the Missouri, for assignment to duty. S. O. 209, A. G. O., September 5, 1884.

LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 13, 1884.

HEYL, T. C., surgeon. September 8, 1884, from the Adams and to the Receiving Ship Independence, Mare Island, Cal.

OPEN TO UNIVERSAL COMPETITION.

THE Cartwright Prize of the Alumni Association of the College of Physicians and Surgeons of New York is open to the competition of alumni of *any* medical college.

It consists of a prize of *five hundred dollars*, to be awarded to the best medical essay submitted upon any subject the writer may select. The award will be paid as soon as the successful article shall have appeared in print.

If no one of the competing essays be deemed sufficiently meritorious the prize is not awarded. An essay, in order to be held worthy of the prize, must contain the results of original investigations made by the writer.

An award of this prize will be made at commencement, 1885. Essays must be sent to a member of the prize committee before April 1, 1885.

Competing essays must each be marked with a device or motto, and accompanied by a sealed envelope, similarly marked, containing the name and address of the author.

R. W. AMIDON, M. D., Chairman, 18 W. 21st St.,
ROBERT ABBE, M. D., 32 East 20th St.,
WALTER MENDELSON, M. D., 209 W. 46th St.,
Committee on Prize Essays.

ERRATUM. — In the note appended to the chart in Dr. Boardman's paper, on page 247 of the last issue of this journal, read The sign *o* indicates a dejection (not an injection).

BOOKS AND PAMPHLETS RECEIVED. — Practical Manual of Diseases of Women and Uterine Therapeutics. For Students and Practitioners. By H. Macnaughton Jones, M. D., etc. New York: D. Appleton & Co. 1884.

Excision of the Rectum for Cancer. Operation. By Walter Coles, M. D., St. Louis, Mo. (Reprint.)

Old and New Codes. By A. M. Wilder, M. D. Read before the California State Medical Society, April 16, 1884.

Hospital Sunday and Hospital Saturday. Their Origin, Progress, Development, etc. By Henry C. Burdett. London, Kegan Paul, Trench & Co. 1884.

Preventable Blindness. By Samuel Theobald, M. D., Chairman Section on Ophthalmology, Otology, and Laryngology. Reprint from Transactions of the Medical and Chirurgical Faculty of Maryland. 1884.

Original Articles.

AMPUTATIONS AT THE RHODE ISLAND HOSPITAL FROM 1868 TO 1883.

BY EDWARD T. CASWELL, M. D.,
Surgeon to the Hospital.

THE following tables present the statistics of all the major amputations performed at the Rhode Island Hospital for the fifteen years that have elapsed since the opening of the hospital, October 1, 1868. The record closes with September 30, 1883, and includes the results of three cases then remaining in the hospital. The whole number of cases is, of course, small, and it is not to be supposed that their presentation will add to or alter the well-known and established principles applicable to these operations. Recognizing the uncertainty of figures and the prevalent belief that statistics are unreliable, I still think that any such collection of data possesses a certain degree of interest, and can afford instruction to every surgeon whose labors are in the same field. Both successes and failures have alike their lesson. At all events, they show something of the work accomplished by the hospital. In the earlier years of its existence this hospital, the first of its kind in the city of Providence, had to win its place in popular favor, and to overcome more or less opposition and distrust. As a consequence it will be seen that in the earlier years the number of cases brought to the hospital demanding operation were comparatively few. Its position now has become firmly established, and with the growth of the city and the increase of varied manufacturing interests it is more than probable that the next decade will see it taxed to its utmost capacity.

The operations have been tabulated under the heads of Traumatic Primary, including a period of less than forty-eight hours, Traumatic Secondary, at any time after that period, and Pathological. For the sake of convenience I have used the numbers 1, 2, 3, to designate respectively the upper, middle and lower thirds of a limb, and the junction of two thirds has been expressed thus: 1 — 2. Any one who has had occasion to look up hospital records will probably appreciate the dissatisfaction that is felt by the compiler when he finds that his blanks cannot all be filled. Sometimes the side of the body is not specified; the cause of the injury is not always given; frequently the method of operating is entirely ignored, and in some cases of death the cause of death is passed over. The latter blank I have filled according to my best judgment, after a careful study of the case. Double amputations and reamputations have been included under their appropriate heads, with cross references. I have said that the list is of the major amputations, but nine operations upon the foot are included.

The Lister method and dressings were first used in the hospital in February, 1878. Since that date very many of the operations have been done according to the various modifications of that method that have been in vogue. The two chief points of Listerism, drainage and cleanliness, have been faithfully sought by all the surgeons of the staff. Some have had more decided views than others as to antiseptic treatment. No attempt has been made to institute a comparison between the methods of treatment in this respect, as the number of cases was so small, and the results of such large experience are already matters of record. The various antiseptics, carbolic acid, thymol, boracic acid, phenol, iodoform, chlorinated soda, and corrosive sublimate have all been used. The spray has been rarely used, if at all, during the last few years.

The results of treatment compare, perhaps, favorably with those of other hospitals, although it seems as if they ought to have been better when we consider the salubrious situation of the hospital, the possession of large and well-ventilated wards, and the freedom from overcrowding which has generally existed. But it must be remembered that most of the accidents are caused by railroads and machinery, and are often of so severe a nature that the best efforts of the surgeon will prove fruitless.

With these preliminary statements I pass to the tables. There have been 123 operations performed on 111 patients. There were nine cases of double amputation, and there were three cases of reamputation, all of which will be found in detail in the summary. One case of traumatic secondary of the thigh is not included: the operation was repeated for secondary hæmorrhage not controlled by ligature. And in the last recorded case of double amputation, the only one of both legs, both stumps were reamputated, but the second operation was subsequent to the period at which this record terminates.

Of 123 operations 57 were traumatic primary, 26 traumatic secondary, and 40 pathological. Of the 111 patients operated upon 24 died, or 21.62 per cent. Of the primary there were 51 cases with 11 deaths, or 21.57 per cent.; of the secondary 22 cases with eight deaths, or 36.36 per cent.; and of the pathological 36 cases with five deaths, or 13.88 per cent. There were two cases of double amputations, in which one operation was primary and the other secondary, and both cases recovered. Classing together the operations for injury we have 73 cases with 19 deaths, or 26.03 per cent. The causes of death will be found in the Summary, tabulated both as to the limb amputated and the nature of the operation.

AMPUTATION AT THE SHOULDER-JOINT. TRAUMATIC PRIMARY.

No.	Sex.	Age.	Date of Admission.	Nature of Injury.	Cause.	Method.	Result.	Date of Discharge.
1	M.	13	July 28, 1869.	–	Machinery.	–	Recovered.	Oct. 8, 1869.
2	M.	10	Feb. 28, 1882.	R. Compound fract. arm and exten. laceration.	Cotton mill gear.	Double flap.	Recovered.	April 17, 1882.

Recovered, 2.

			Death-rate.
Primary	51 cases.	11 deaths.	21.57 per cent.
Secondary	22 cases.	8 deaths.	36.36 per cent.
Primary and Secondary	2 cases.	–	—
	75 cases.	19 deaths.	26.03 per cent.
Pathological	36 cases.	5 deaths.	13.88 per cent.
Total	111 cases.	24 deaths.	21.62 per cent.

Although these numbers are small it may not be uninteresting to compare them with the statistics given by Dr. Ashhurst in the International Encyclopædia of Surgery, and by Professor Agnew in his work on Surgery: —

ASHHURST.

	Death-rate.
Total, 6448 cases	32.9 per cent.
Injury, 3024 cases	39.8 per cent.
Disease, 3424 cases	26.8 per cent.

AGNEW.

5956 cases	32.42 per cent.
Primary, 2572 cases	35.81 per cent.
Secondary, 781 cases	50.19 per cent.
2603 cases	23.74 per cent.

Dr. Agnew also gives the mortality of all amputations at the Pennsylvania Hospital for the years 1870–1878 as 21.43 per cent. in 252 cases. It is more than probable that the next ten years will witness in all well-managed hospitals a decided diminution in the death-rate following amputation.

PROVIDENCE, *April* 11, 1884.

TWO CASES OF GENERAL CHRONIC PROCTITIS

CAUSED BY RETROVERSION OF THE UTERUS WITH PROLAPSE OF RIGHT OVARY IN THE FIRST CASE, BY SIMPLE RETROVERSION OF THE UTERUS WITH CHRONIC ENDOMETRITIS IN THE SECOND CASE.

BY F. W. JOHNSON, M. D.,
Surgeon, Out Patients, Free Hospital for Women.

INFLAMMATION of the rectum involving the mucous, submucous, and muscular layers of the gut is of quite frequent occurrence in women suffering from some acute or chronic affection of the ovaries, tubes, uterus, or vagina. The onset of the attack is not marked. According to my experience, limited to six cases, the inflammation does not begin as an acute proctitis which gradually subsides into the chronic form, but from a feeling of burning and weight in the rectum with perhaps some backache, frequent micturition, watery stools soon after rising in the morning, followed by a feeling as if the rectum had not been emptied, it gradually increases until the patient is driven to the physician complaining of loose muco-purulent dejections which are sometimes mixed with blood, tenesmus, frequent and painful micturition, sometimes retention, con-

stant pain and burning in the rectum, leucorrhœa, dysmenorrhœa, acute attacks of indigestion, accompanied at times, as in Case No. II., with stercoraceous vomiting, and inability to stand or walk with any comfort. There is loss of flesh, restless nights, and general impairment of health. This condition, varying in severity, may last for a long time, but eventually ends, if left to itself, in infiltration and thickening of the rectal wall. It may end in ulceration involving the whole thickness of the mucous membrane. It may involve the mouths of the tubular follicles causing ulceration and perforation of the bowel. It may cause an abscess which may result in fistula, and it is a frequent cause of stricture. Very little has been written on general or localized chronic proctitis occurring secondarily to some affection of the uterus or its appendages. It was only in the work of Charles B. Kelsey that I was able to find anything satisfactory on the subject.

CASE I. Mrs. W., twenty-seven, married, born in Boston of German parents. Mother insane. Menstruation began at thirteen. Always regular every four weeks until seven years ago, since which time has been irregular, going five, six, and seven weeks without menstruating. During the past seven years has had dysmenorrhœa. The pain, confined to the ovarian regions, begins six to eight days before the flow, and lasts during the first day. Flows six days and saturates seven to eight napkins. No clots. Has never been pregnant. Frequent pain and almost constant feeling of pressure at the top of the head. Constant pain in sacral region, increased by walking or standing. Constant burning and feeling of pressure in the rectum. Leucorrhœa white and thin in character. Appetite poor. All kinds of food cause distress. The right ovary was prolapsed into Douglas's pouch; was enlarged to the size of an English walnut, and was very sensitive. The uterus was retroverted, sensitive at the fundus, and was prolapsed in the first degree. The rectal mucous membrane was much thickened, of a dark-red, almost purple color, and covered with an abundant muco-purulent secretion. Sphincter ani unyielding, no eversion of rectal mucous membrane, and no dilatation of the hæmorrhoidal vessels.

In this case the evacuations numbered ten to twelve each day and consisted of muco-purulent material, at times mixed with fæcal matter, and always attended with more or less pain. When fæcal matter was present the stools contained blood. Each evacuation was attended with tenesmus and sharp pains through the pelvis. There was frequent and painful micturition. Most of the above symptoms, though less severe, had been present for six months. During this time she had used suppositories containing iodoform, tannin, and morphia, enemas of starch and laudanum, and various drugs by the mouth. She said the iodoform did the most good, but she would not continue its use on account of the offensive odor it gave to the evacuations. After my examination she was put on the following course of treatment: Every fifth night she took of hydrarg. cum creta eight grains, followed in the morning by a saline cathartic. Three times a day two quarts of hot water as hot as could be borne (she was able in ten days to use water at a temperature of 140° F.) were injected into the rectum through a vaginal nozzle, while reclining on the left side with a thick pillow under the hips. This position was insisted upon in order that the rectum might be ballooned out, and as much as possible of its mucous membrane brought in contact with the hot water. The same position was maintained for twenty minutes after the injection was completed. The diet consisted principally of milk with stale bread. All vegetables, except lettuce, tea, coffee, beer, and wine were forbidden. In two weeks, time great improvement took place. The sensitiveness of the right ovary and fundus uteri had gone, and I was able to replace them and keep them where they belonged by a Thomas' retroflexion pessary, the bulb of which was made large enough to fill the posterior cul de sac, and thus prevent the ovary from prolapsing. Improvement was rapid, with now and then a drawback due to her own carelessness. On one occasion she was thrown down while skating, and as a result the pessary was forced part way outside the vagina, the fundus flexed over the posterior bar, and the right ovary again prolapsed. It was two weeks before the sensitiveness diminished enough to allow the replacing of the pessary.

During the two weeks before the pessary was adjusted the rectal symptoms improved very much, but after the pessary was put in place the improvement in the rectal symptoms was simply astonishing. The evacuations were soon reduced to two each day. The tenesmus, pains throughout the pelvis, dysmenorrhœa, dyspepsia, and painful micturition soon departed. It is now three months since the treatment was begun, and she considers herself perfectly well.

CASE II. Miss D., twenty-five, single, born in this State, family history phthisical. A few years ago she went through a long and hard siege of neurasthenia. She was one of those fat, anæmic, flabby individuals, who so often fall victims to nervous exhaustion.

The rectal symptoms were heat and burning, sharp, shooting pains, frequent and, at times, painful evacuations, containing blood and mucus, and backache. There was no tenesmus. All these symptoms were worse during menstruation. Frequent attacks of indigestion at menstrual periods, accompanied, as I mentioned above, with stercoraceous vomiting, requiring morphine for its relief. This condition had lasted for three months. Menstruation first appeared at twelve. Menstruates each twenty-five to thirty-one days. Flows seven days. Uses fourteen napkins, and saturates seven to eight. Dysmenorrhœa during the third and fourth days, the pain being in the lower part of the abdomen in front, and in the right ovarian region, confining her to bed. Frequent dizziness. Almost constant pain in right ovarian region, which is increased on walking. Constant bearing down when standing. Persistent vaginal discharge; slight in quantity, thick, and brownish-white. Frequent and painful micturition. Appetite poor. Digestion poor. Vagina large and relaxed. Uterus low down in the pelvis, retroverted and enlarged throughout, with a cavity measuring three inches. Cervix rested on the floor of the pelvis, and admitted index finger to internal os. External os eroded. Secretion from cervix muco-purulent, and of a brown color. Internal os and fundus uteri very sensitive. She was put on the same course of treatment as the other patient, except that she was given one fiftieth of a grain of valerianate of strychnia and one fiftieth of a grain of arsenious acid three times a day. She began to improve from the first, and in one month's time a Thomas' retroflexion pessary was adjusted, and the improvement has been uninterrupted.

How long it will take to cure the chronic endometritis with the attending areolar hyperplasia, which I

consider to be at the bottom of the trouble, it is very difficult to say. In Case I. my theory is that retroversion took place about seven years ago, accompanied with ovarian disturbance, and these were the cause of the dysmenorrhœa; finally the right ovary prolapsed into Douglas's pouch, and as a consequence rectal trouble was set up. In Case II. the chronic endometritis produced areolar hyperplasia; the uterine ligaments being inadequate to support the enlarged and heavy uterus, retroversion ensued; with the retroversion ovarian disturbance was set up, and as a result dysmenorrhœa and proctitis were developed.

The subject of Case I. is able to do her own housework and keep her husband's books, while before she had treatment she could not be on her feet long enough to get breakfast. Menstruation is still irregular, but it comes on without any pain; in fact, the appearance of the flow is the first indication she has that she is unwell.

AMPUTATIONS AND ARTIFICIAL LEGS.

BY D. DE FORREST DOUGLASS, SPRINGFIELD, MASS.

Manufacturers are constantly called upon to make and adjust artificial legs to stumps where amputation was performed by the "rules" taught in works on surgery previous to the modern invention and great improvements in the construction and adjustment of artificial legs.

The two *professions* should coöperate for the welfare of the patient, where so much is depending upon the point of amputation. It should be the leading thought with the medical profession not only how skillfully can it be performed, but how well the patient can be fitted for the duties and burdens of life, how well the chasm between the natural and artificial can be bridged, how well the adjustment be made where the natural ends and the artificial begins.

The absolute "rule" laid down in the works on surgery — in amputations always to save as much as possible — has had and passed its day of usefulness. It had its origin in the earliest days of surgery, when an amputation was attended with much greater risk of life than at the present time with such great improvements in the practice of the profession.

Previous to the invention and application of artificial legs the loss of a member, or any part of it, was looked upon by the patient as a great affliction, and he enjoined upon the surgeon to save as much as possible, as he feared both the result of the amputation and physical appearance. It was a natural and spontaneous feeling, the growth of surrounding circumstances.

While it may or may not be correct that the longer the stump the less liable to fatal results, there are other considerations which should have weight and influence with surgeons. If the saving of a life is desirable, life should be desirable after it is saved. If through the great kindness and zeal of the surgeon he has saved the life of his patient, and has at the same time entailed upon him a condition preventing him from the enjoyment of the full or partial duties of life, he has saved it, but full of bitterness.

An experience of more than thirty years with patients who have submitted to amputation has shown this important fact, that the last and most absorbing thought previous to the operation would find expression in, "Doctor, give me the very best stump to wear an artificial leg," showing life a secondary consideration unless made desirable.

I would, therefore, suggest, as giving the best results to the patient, not only immediate but during the subsequent time the artificial must coöperate with the natural member, first, never to amputate through the joint. In these cases the stumps are almost invariably thinly covered at the end; from necessity, the tissues not being abundant, the circulation is feeble, vitality at the extreme end much reduced, and the liability to excoriation is great. The power in using an artificial leg is reduced in the same ratio that the stump is enfeebled or sensitive, and the value and usefulness of the leg enhanced the more nearly we approach the right point of amputation.

It is impossible, in amputations at the joint, to construct an artificial appliance that will so well supply the loss, symmetrically or in durability, as in amputations in the continuity, and never is it so satisfactory to the patient.

Artificial legs are fitted to such amputations because they are presented for treatment, and the patient has walked well. But this proves nothing. Compare these with leg or thigh amputations after two or three years' experience, and the result will be quite different from what would appear at first. Many cases result in a secondary amputation.

We frequently meet stumps showing fine skill in the art of surgery, none finer *of the kind* could be made, but unfortunately made at the wrong point.

Another and a serious objection is that the space occupied by the remaining portion of joint is required for a properly constructed artificial joint. Both cannot occupy the same space.

Nearly the same objections will apply to extremely long stumps, either of leg or thigh, — feeble circulation at the end, low vitality, danger of excoriation, and therefore slow process of healing. Long stumps are liable to swell at the end, and the artificial leg is required to be made larger at this point to meet the difficulty.

After passing nine inches below the lower edge of the patella, we make no use of the stump either for bearing or propelling power. Therefore as considerations of utility, safety, usefulness, and symmetry in the artificial leg, long stumps are undesirable. The best length of stump for thigh amputation is ten inches, measuring inside from body.

Of course the conditions of injury or disease determine shorter stumps. But the rule stands the same, and the more nearly it can be conformed to the better the results.

In all cases of anchylosis of knee-joint, flexed at right angles, the end of stump should fall one inch back of a line of the thigh. Such cases are well adapted for a leg with bearing on the knee. In these cases a greater length of stump is undesirable, as the perfect outline of the patient when dressed would be broken by a protruding stump.

The most desirable method of amputation, giving the best stump, capable of exerting the greatest power of locomotion, leaving the tissues the more nearly in their natural position and condition, and the least liable to injury or excoriation, is the anterio-posterior flap operation.

TREATMENT OF STUMPS.

It will be proper to remark in connection with this subject, that after a stump is well healed — to put it in the best condition for the application of an artificial leg, — it should be constantly bandaged as tightly as can be comfortably worn for four or five weeks. This renders it more conical in form, better adapted to sustain the weight of body on the artificial leg.

These observations and suggestions are the result of, and are based upon, a thorough practical experience of over thirty years in making and adjusting artificial legs to every form of stump.

CASE OF ACUTE DIABETES OF UNKNOWN DURATION; DEATH FROM COMA SEVENTY-TWO HOURS AFTER COMING UNDER OBSERVATION.[1]

BY DR. O. F. ROGERS.

THE patient was a rather pale and fleshy gentleman of forty-four years, possessed of abundant means, and previously in good health. His business gave him little labor and no anxiety. His habits were correct. On the evening of the 21st of December, 1882, he was out late and got thoroughly chilled. The next morning he had a sore throat.

On the evening of the 24th he called me to prescribe for his throat and to advise him whether or not to drive several miles the next day to fulfill a Christmas dinner engagement. He was in his parlor when I called, and gave me a brisk and cheerful greeting. The throat was of a dark-red color, the uvula and left faucial pillars were œdematous, and the left tonsil was somewhat swollen. A few herpetic patches were noticed upon the anterior pillar of the right side and upon the velum palati. The lips and nose were liberally strewn with herpes. There was slight dysphagia. The pulse was 120, and rather weak; the temperature 99° F.; the bowels were regular; the appetite impaired. He felt neither sick nor well. I remarked upon the feebleness and frequency of his pulse, and was told that for years this symptom had invariably accompanied a sore throat. I ordered a milk diet, one ounce of gin, and a dose of tincture ferri chloridi every three hours, and recommended him to go to bed.

On the 25th he said he felt better. The pulse was 124, and the temperature 98.6° F. The throat had not materially changed in appearance. He took an abundance of milk, and the gin and iron as ordered.

On the 26th the swelling and œdema of the left side of the throat had nearly disappeared; the right tonsil was now somewhat swollen, and there were several aphthous spots upon the mucous membrane of the gums and cheeks. He remarked that his mouth was dry, and repeatedly rinsed it with water and took frequent sips of milk or lemonade. He was rather restless, and asked for a half dozen things while I sat by him. He sat up in bed and was lively and talkative, and much interested in showing me a beautiful musical toy. He said that he felt better, but he did not look so. His features were drawn and the countenance grayish, and he seemed to have wasted since the evening of the 24th.

[1] Communicated to the Dorchester Medical Club, July 21, 1884.

Though his appearance disquieted me, I could not bring myself to believe that he was seriously ill. Later in the day I sent for a specimen of his urine, though I had not the slightest suspicion of the nature of his illness. The urine was of a specific gravity of 1.035, and contained eighteen grains of sugar to the ounce, and a trace of albumen.

I was informed by his attendants that he had during the past few nights — exactly how many they could not say — filled a chamber-pot with urine; also that he had urinated frequently and largely during the day. He evidently was passing a gallon of urine a day. He made about half his usual quantity of urine and was somewhat restless during the night, and complained of slight pain in his abdomen. His bowels were regular, though slightly constipated.

At five A. M. of the 27th he appeared to be dazed, was incoherent and indistinct in speech, and shortly afterward began to breathe heavily. At seven A. M. he knew and spoke to me, but soon became completely comatose, breathing deeply and loudly but not snoring. The pulse was 140 and weak. He now passed urine for the last time. This gave the so-called acetone reaction with the tincture of chloride of iron.

At ten A. M. Dr. D. W. Cheever, who had attended him in the city, saw him in consultation. He was then absolutely unconscious, and the pulse barely perceptible at the wrist. The breath had a sweetish, hay-tea odor; later on it smelt like fresh ensilage. During the whole day he lay unconscious, never moving, his face pale and skin moist and cool, breathing deeply and regularly and with great force, while the heart beats grew feebler and more frequent.

About a half an hour before death the intervals between the respirations became longer, and finally there was irregularity. Then for the first time cyanosis was observed.

Death occurred at five P. M., just three days after he came under treatment, and rather less than six days from the time of the exposure to cold.

The question of duration of the disease in this case is one of much interest. I believe it was a matter of days and not of weeks. He believed himself to be perfectly well on the 21st December, but there is evidence that he had been passing an unusual quantity of urine for a few days before that date. Three days before his death he had not perceptibly lost flesh, there was but slight diminution of strength, and it was not till the day before his death that his appearance indicated that he was seriously ill. Cases of acute diabetes presenting a history similar to this are very rare indeed.

A knowledge of the early symptoms and the predisposing and exciting causes of coma in diabetes is of prime importance to the practitioner. It is most apt to occur in young subjects and in acute cases. Nervous excitement, exposure to cold, muscular exertion, and constipation are predisposing causes. Frequency of the pulse, restlessness, abdominal pain, and deep respiration are the earliest premonitory symptoms of coma (Foster and Saundby). Sometimes a sudden diminution in the quantity of the urine and fall of the specific gravity have been noticed before the attack. The sudden appearance of albumen is of grave import, though it is by no means necessarily followed by coma.

Pharyngitis and red, spongy gums, associated or not with aphthæ, are sufficiently frequent in the later stages of diabetes to warrant the conclusion that they are a manifestation of the diabetic dyscrasias. There-

fore I venture the remark that when these symptoms are observed, and especially if they are attended by a weak and rapid pulse, an examination of the urine is indicated just as it is indicated by carbuncle, and perhaps to a greater degree.

The coma in this case was not treated, because I believe the condition has as yet no therapeutics.

A CASE OF MENSTRUATION RECURRING EVERY THREE MONTHS,

ATTENDED WITH SEVERE DYSMENORRHŒA, FOR TWENTY-SEVEN YEARS, COMPLICATED BY HYSTERIA AND NEURASTHENIA. RECOVERY.[1]

BY GEORGE H. BIXBY, M. D., BOSTON

Mrs. F., widow, aged thirty-eight, native of New Hampshire, was admitted to the Carney Hospital September 25, 1882. She had traveled eighty miles by rail, reclining upon a mattress. She was allowed to rest four days.

Family History. On father's side long-lived and intellectually endowed. Several deaths from phthisis had taken place on the mother's side.

Catamenia first appeared at the eleventh year; continued irregular, scanty, and of short duration. In early childhood, up to the time of the appearance of the menses, she suffered from habitual constipation. She became a teacher in her sixteenth year. Later she entered a normal school as a pupil, but before the close of the first term from sheer debility was obliged to leave. During the vacation she was suddenly seized with a fit of spasmodic coughing, which persisted three hours without interruption. This attack was not regarded as anything serious at first, but later proved to have made a profound impression upon her general health. A cough of a similar character occurred later, but of shorter duration. A few months of absolute mental and physical rest seemed to have restored her health. In 1870 she was married. She was now able to attend to all her domestic duties, if not overtaxed. Any great excitement, however, would induce a peculiar muscular contraction in the dorsal portion of the spinal region, subsiding after a short season of complete rest.

In 1871 these spasms were of frequent occurrence and of longer duration. Spinal anæmia was suspected by the family physician and treated without result.

At this time the most delicate contact with certain portions of the spine would call forth the most violent convulsive movements of the entire body, lasting at least a half hour. For three months she was confined to her bed, unable to move without assistance, always in the supine position. After that time she managed to place her feet on the floor, and a month later to walk on a level surface. The act of ascending stairs could only be accomplished by creeping. The spasms never entirely left her. Menstruation appeared at intervals of three months and always attended with sufferings not unlike the pains of labor. She seemed to lose at this period all that she had gained by the long interval of rest.

Between the years of 1871 and 1872 she had two miscarriages. In 1873 she gave birth to a full-grown male child with tedious labor. The child was nursed. After her confinement she gained rapidly; menstruation recurred fourteen months later, scanty and of short duration as of old, but less painful. A month later the death of her husband, after a short illness, threatened at one time a complete relapse. Owing to the decided improvement in her general health she rallied from the blow and continued in tolerably good condition. Two years later she ventured to resume teaching, but was interrupted by another emotional influence, namely, the death of her mother and sister, through whose entire illnesses she had been for months an untiring and devoted attendant. She began to experience loss of power in the spinal region, which caused her without any warning to slide from her chair, regaining strength to raise herself in the course of five minutes. Other members of the family fell ill, taxing her mentally and physically anew.

Early in 1881 cardiac and facial neuralgia ensued, and later sciatica of a most severe form, which necessitated the use of subcutaneous injections of morphia several times daily.

January 25, 1881, she discovered a tendency to contraction in the left knee-joint, already flexing the leg considerably, and which no amount of passive motion could overcome. A month later in standing she rested the affected limb entirely upon the ball of the toe.

Her surroundings and habits during the latter part of this long season of invalidism were as follows: She had received subcutaneous injection of morphia two or three times daily for a year and eight months. A failure to respond to her demands promptly would call forth fits of wild impatience. Mostly confined to her bed, the entire community ministered to her caprices. She received callers in and out of season, and interested herself in all passing events of the neighborhood. She sewed, knit, wrote, and read incessantly. In addition to emotional causes due to domestic troubles there came into the peaceful community a bitter religious war, and unfortunately the leader of this resided under the same roof. It is needless to say that the subject occupied her mind incessantly.

Examination of the Patient. Inspection. The patient is above the average stature, large frame, light complexion, large prominent eyes, hair slightly gray and cut short. A number of decayed teeth are conspicuous in the upper jaw. Face more or less emaciated, all giving her a haggard and careworn expression.

Palpation. Left limb a third smaller than the right, muscles flabby, decidedly atrophied above and below the knee. When she stands erect with back toward one, the left limb rests upon the left great toe. The peculiar raised condition, apparently of the pelvis, forms a picture suggestive of lateral curvature of the spine.

Diagnosis. Neurasthenia, dependent upon functional derangement of the sexual organs, ostensibly ovarian, in the form of amenorrhœa, intensified by repeated and powerful emotional causes.

Prognosis doubtful.

Plan of treatment. Removal from home. Immediate and total suspension of opium. Examination of the sexual organs under ether. Removal of decayed teeth. Preparation of the system for the use of iron. Later, iron treatment. Physical rest; mental rest. Passive exercise. Extra feeding. Straightening of the limb.

[1] Read before the Boston Society for Medical Observation, March 3, 1884.

The patient took her last hypodermic on the day of her arrival. Was allowed a suppository of opium and belladonna five nights in succession. By this sudden removal of the opium some reaction was, naturally, expected. To our great astonishment none whatever took place.

While the patient was under ether for extracting the teeth the sexual organs were carefully examined. There was no evidence of uterine disease except a slight erosion of the cervix.

Milk diet, one quart extra daily to begin with, was given in addition to full diet. Massage and electricity to be applied on alternate days. All mental exercise, such as reading, writing, and conversation, to be avoided. Rest in bed.

With regard to the medicinal treatment, I cannot resist quoting the valuable suggestions of Mr. Robert Barnes[1]: —

"It is accepted as an axiom in medicine that the blood, being deficient in red globules, iron is the remedy *par excellence*. This is true, but it requires more judgment in administering it than is usually shown. Long clinical experience has taught me the general law, that in all states of blood degeneration, whether resulting from malnutrition or wasting disease, as from hæmorrhage, iron is ill tolerated at the beginning. In all extreme anæmic states the febrile irritability I have adverted to is liable to be aggravated by the iron, if rudely and precipitately thrown in, as the phrase is. The tongue gets parched and brown, indicating a like state throughout the alimentary canal, inducing constipation, and generally impeding nutrition. Pulse rises in frequency. The true medication is first to allay vascular irritability, so as to prepare the system to assimilate iron. This is best done by salines, of which the best, I think, is the spir. mindererri. If freshly made, so marked is the benefit ensuing from the use of salines one cannot resist the conclusion that the blood is in want of salines as well as iron, and the salines is the first want. When the vascularity is subdued, when the secretory organs have been brought about, iron may cautiously be essayed."

In accordance with these suggestions the following treatment, preparatory to the use of iron, was ordered: Half an ounce of freshly-prepared liquor ammon. acetat., three times daily, for eight days. To be followed, a week later, by a saturated solution of chlorate of potash, one drachm in a wineglass of water, after meals. Six days later, drachm doses of the elixir of iron, quinine, and strychnia.

This *régime* was carried out ninety-nine days daily without a single omission. Diet of all kinds and medicine gradually increased. November 10th artificial teeth were inserted, making, in a short time, a marked difference for the better in her digestion and assimilation. During the ensuing weeks she improved rapidly. Menstruation, which had been irregular for twenty-seven years, now became regular. The opportune moment now seemed to have arrived for straightening the limb. By the kindness of Dr. E. H. Bradford the operation was undertaken on the 17th of January, in the following manner: —

The patient being deeply etherized the inner and outer hamstrings and tendo-Achilles were cut, and the adhesions in the joint forcibly broken. The anchylosis proved to have been false. The limb was fully extended and placed in a plaster bandage.

[1] Barnes on the Diseases of Women, pp. 167–168.

On the 24th, the plaster being perfectly dry, the patient was ordered to stand erect for a few minutes every day. On the 25th she walked twenty feet. On the 30th the plaster apparatus was removed; straight splint substituted; worn night and day. On the 31st required to flex and extend the knee ten times daily. February 9th, walked a few steps without crutches. February 12th, went down stairs ten steps. On the 15th, two flights of twelve steps each. Henceforth massage and electricity irregularly applied, but active exercise, walking about the apartment with the aid of crutches, up and down stairs, was systematically carried out; mental rest still continued. The improvement continued uninterrupted.

It is a remarkable fact that the next day after straightening the limb there was an entire absence of convulsions, however roughly the spine was manipulated. She was taking, in addition to full diet, at least three quarts of milk daily.

April 5th, after having been in the hospital seven months, still relying on her crutches, she went home, occupying a seat in an ordinary passenger car, and sitting erect. The journey ended by a drive of four and one half miles, by stage, over a very rough road.
